## VITAE

Wayne M. McDonald, son of Dr. William J. McDonald and Virginia M. Leritz, was born January 25, 1974, in West Palm Beach, Florida. He graduated from Cardinal Newman High School in 1992. Subsequently, he attended Auburn University, Alabama, and graduated in December, 1998 with a Bachelor of Science degree in Geology. He worked as an environmental consultant for a few years and then entered Graduate School, Auburn University, in August, 2003.

THESIS ABSTRACT

$^{40}\text{Ar}/^{39}\text{Ar}$  AGES OF MUSCOVITE FROM THE WESTERN BLUE RIDGE AND  
TALLADEGA BELT, GEORGIA AND NORTH CAROLINA

Wayne M. McDonald

Masters of Science, May 10, 2008

Radiometric age constraints regarding the timing of metamorphism in the western Blue Ridge province of the southern Appalachians have been too limited or uncertain to enable broader correlation and understanding of Taconian, Acadian, and Alleghanian events in the region between western North Carolina and Alabama. Moreover, various fossil, stratigraphic and radiometric data for the timing of metamorphism in the Talladega belt of Alabama are difficult to reconcile with radiometric ages of comparable tectonic units in the western Blue Ridge of North Carolina. New  $^{40}\text{Ar}/^{39}\text{Ar}$  radiometric data for single-muscovite crystals have been collected, utilizing the Auburn Noble Isotope Mass Analysis Laboratory (ANIMAL), to help constrain the timing of metamorphism in the western Blue Ridge of Georgia and North Carolina. The mean ages of muscovite in

phyllites collected from the Cartersville transverse zone record crystallization and cooling in the interval from  $321.4 \pm 0.3$  -  $335.5 \pm 0.8$  Ma (corresponding to Serpukhovian and Viséan stages of the Mississippian). The mean ages of muscovite in three phyllites from a sampling transect along U.S. Hwy. 64 (between Murphy, North Carolina and Ducktown, Tennessee) are similar to those of the Cartersville transverse zone. However, the age distributions of single-crystal muscovite in six other schists and phyllites from this Murphy-Ducktown transect are complex, with ages ranging up to ca. 465 Ma. The mean ages of muscovite in metasiltsstones and phyllites collected within or near the Great Smoky fault (between the Murphy-Ducktown transect and the Cartersville transverse zone) also tend to be Viséan. However, several samples from this tectonic setting also yield very complex age distributions. The complex age distributions determined in this study seem mainly due to effects of polymetamorphism in some rocks, but are also influenced by the presence of relict-detrital muscovite and incorporation of unsupported-extraneous ('excess')  $^{40}\text{Ar}$  in some samples. The single-crystal  $^{40}\text{Ar}/^{39}\text{Ar}$  ages determined in this study are interpreted to indicate that Mississippian tectonic events dominated metamorphic and structural evolution in the Talladega belt and in the Mineral Bluff Group of the western Blue Ridge. For Ocoee Supergroup rocks, in the western Blue Ridge, the muscovite in phyllites and schists record a history of pre-Carboniferous (Acadian or Taconian) events partially overprinted by Mississippian deformation. The Mississippian ages are interpreted to represent Alleghanian events recorded in the muscovite of Talladega belt-western Blue Ridge rocks that pre-date final emplacement of the Blue Ridge thrust sheet, as the youngest deformed strata of the Valley and Ridge (Pottsville Formation; 316-303 Ma) indicates Pennsylvanian deposition. This combined

with Tournaisian fossil control (*Periastron* plant fossil; 360-350 Ma) indicates Alleghanian metamorphism and deformation in the Talladega belt-western Blue Ridge is constrained to ~ 360-300 Ma, older and longer in duration than the classic view of the Alleghanian as Pennsylvanian to Permian.

## ACKNOWLEDGEMENTS

The National Science Foundation funded this study and provided financial assistance to the author for one year. Special thanks to Dr. Willis Hames for the opportunity to work on this study and his effort to see it through. Thanks are also due to committee members Dr. Luke Marzen, for assistance with the GIS, and Dr. Mark Steltenpohl, for help with understanding structural aspects of this study. Also worth noting are Dr. Ashraf Uddin and Dr. Charles Savrda for their moral support and general guidance, John Simms for his almost daily assistance with various things, and Dr. Mehmet Billor for many helpful discussions. Thanks are mostly due to family members William and Virginia whose financial support made working on this study a possibility.

## INTRODUCTION

The western Blue Ridge and Talladega belt (Figure 1) together represent the leading thrust belt of the southern Appalachian metamorphic core and consist primarily of low-grade metasedimentary rocks. These rocks were deposited as shallow marine sediment along the eastern-coastal margin of Late Proterozoic to Paleozoic Laurentia. Subsequently, these sediments were metamorphosed and thrust cratonward over younger sedimentary rocks through several orogenic events of Paleozoic Appalachian evolution (Williams and Hatcher, 1982; Thomas, 1983; Hatcher, 1987; Hatcher, 1989; Horton et al., 1989; Tull and Holm, 2005).

The tectonic history of the western Blue Ridge in northwest Georgia is unclear, and its relationship to well constrained southern Appalachian events elsewhere is uncertain. Research in the Smoky Mountain region of the western Blue Ridge indicates a Taconian and Acadian dominated tectonic history (Connelly and Dallmeyer, 1993; Kunk et al., 2006). Geologic studies in the Talladega belt of Alabama indicate an Alleghanian dominated tectonic history (Gastaldo et al., 1993; Steltenpohl and Kunk, 1993; McClellan et al., 2005; Steltenpohl, et al., 2005; McClellan et al., 2007). This thesis focuses on constraining timing limits of metamorphism and cooling in the western Blue Ridge of Georgia by  $^{40}\text{Ar}/^{39}\text{Ar}$  radiometric dating of muscovite and how it relates to the tectonic history known for adjacent regions.

Figure 1: The southern Appalachians depicting the Talladega belt-western Blue Ridge and other tectonic units as labeled (modified from Gastaldo et al., 1993). The inset boxes indicate areas of previous geochronologic research: 1) Connelly and Dallmeyer (1993), Ordovician-Silurian (Taconian) and Late Devonian (Acadian) tectonics; 2) Steltenpohl and Kunk (1993), McClellan et al. (2005) and Steltenpohl et al. (2005), Carboniferous (Alleghanian) tectonics. Yellow triangles indicate approximate sampling locations for this thesis. Red circle indicates location of an Early Mississippian (Tournaisian) *Periastron* plant fossil reported by Gastaldo et al. (1993).

Muscovite is a relatively plentiful mineral in the metasedimentary and meta-igneous rocks of the western Blue Ridge. Furthermore, it is amenable to  $^{40}\text{Ar}/^{39}\text{Ar}$  dating, as the growth of this mineral can usually be placed in the context of a sample's structural evolution, has a closure temperature conducive for dating low to moderate temperature events, and is relatively insensitive to problems associated with extraneous argon (McDougall and Harrison, 1999). Radiometric ages for muscovite could represent the timing of metamorphism, the timing of cooling to a temperature at which radiogenic argon accumulates ("closure temperature;" see Dodson, 1973), or the timing of deformation at low metamorphic grade (e.g., Dunlap, 1991). The cooling history has important implications for the accumulation of radiogenic argon. A rapid cooling history for a rock sample gives similar age dates for different minerals with relatively high closure temperatures. Slow cooling rates give a range of age dates due to different mineral closure temperatures.

Thirty-two samples of lower-greenschist facies rocks were collected, based on regional setting and petrography, from the Talladega belt-western Blue Ridge (Georgia, North Carolina, and Tennessee; Figure 1). The study areas include 1) the Cartersville Transverse Zone, 2) the Blue Ridge thrust front in northwest Georgia, and 3) a sampling transect from Ducktown-Tennessee east through the Murphy synclinorium in North Carolina. The samples were analyzed petrographically to verify whether the rocks have a simple metamorphic history or evidence of polymetamorphism. A web-enabled GIS was constructed for use as a database for sample and research locations, and to make the radiometric data readily available to other researchers.

## **GEOLOGIC SETTING OF THE SOUTHERN BLUE RIDGE PROVINCE**

The southern Appalachian orogen culminated in the Paleozoic from a series of contractional events (Figure 2) along the eastern margin of Laurentia (Thomas, 1983; Hatcher, 1987). These orogenic events follow the processes of a complete Wilson cycle (Wilson, 1966). The evolution of the southern Appalachians (Figure 3) began with Late Proterozoic continental rifting and formation of a subsiding passive continental margin into the Early Paleozoic, followed by later Paleozoic plate convergence and accretion of rifted-terrane fragments and island-arc terranes, finalized by continent-continent collision (Hatcher, 1989).

### **REGIONAL GEOLOGY**

The Cumberland Plateau and the Valley and Ridge represent the Appalachian foreland. The Appalachian metamorphic core comprises, from west to east, the western Blue Ridge and correlative Talladega belt, the eastern Blue Ridge, the Inner Piedmont, and peri-Gondwanaland arcs of the Carolina terrane (Figures 1 & 3).

The Cumberland Plateau represents the westernmost Appalachian deformation belt and consists of gently folded, Paleozoic sedimentary rocks (Rodgers, 1970). To the southeast the Valley and Ridge (foreland fold and thrust belt) overlies the Cumberland Plateau and consists of intensely folded and faulted Paleozoic-sedimentary rocks (Weaver, 1970).

Figure 2: Timing of major events in the tectonic evolution of the southern Appalachians (modified from Hatcher, 1987).

Figure 3: Main tectonic events in schematic cross-sections depicting evolution of the southern Appalachians (from Hatcher, 1987).

The Valley and Ridge was thrust cratonward by thin-skinned decollement, foreland thrusting (Hatcher and Odom, 1980).

The westernmost metamorphic belt of the southern Appalachians and easternmost occurrence of Laurentian rocks is represented by the western Blue Ridge, in northwest Georgia and western North Carolina, and the Talladega Belt, in west-central Georgia and east-central Alabama (Tull and Holm, 2005). The western Blue Ridge and Talladega belt were originally deposited on the Late Proterozoic to Paleozoic, rifted to passive margin along the eastern margin of Laurentia and western shoreline of the Iapetus Ocean (Williams and Hatcher, 1982). These terranes consist primarily of lower-greenschist facies metasedimentary rocks and Grenville basement that were thrust upon Paleozoic sedimentary rocks of the foreland fold and thrust belt along the Talladega – Cartersville – Great Smoky fault (Horton et al., 1989). The western Blue Ridge and Talladega belt preserve the initial and subsequent metamorphic history of the southern Appalachians.

To the east, amphibolite-facies crystalline rocks of the eastern Blue Ridge were thrust upon western Blue Ridge and Talladega belt rocks along the Hollins Line – Hayesville fault (Horton et al., 1989; McClellan et al., 2005). The eastern Blue Ridge is interpreted as the accretionary wedge that resulted from accretion of the Piedmont Arc to Laurentia (Hatcher, 1987). The eastern Blue Ridge consists primarily of metamorphosed distal-clastic rocks deposited off the eastern Laurentian margin as slope-rise sediments, fragments of oceanic crust, mafic bodies, felsic intrusives, and Grenville basement (Hopson, 1989). The major Paleozoic phases of the southern Appalachian Orogen (Hatcher, 1987, and discussed below) include the Taconian, Acadian, and Alleghanian orogenies.

## **TACONIAN OROGENY**

Middle Ordovician to Early Silurian (ca. 480-430 Ma) plate convergence resulted in the initial closing of the Iapetus Ocean and production of a system of thrust faults (Drake et al., 1989; Horton et al., 1989). This included partial subduction of the Laurentian margin and minor obduction of oceanic crust. Accretion of an Early Ordovician arc terrane (Piedmont Terrane) to the Laurentian margin resulted in thrusting of Late Proterozoic to Cambrian Laurentian-margin terrane cratonward over Laurentia. An Appalachian foreland basin formed due to tectonic loading and eroded sediment was deposited as a clastic wedge over the Cambrian, Appalachian platformal margin (Thomas, 1977; Drake et al., 1989). The Taconic clastic wedge is represented by the Blount and Martinsburg formations in the central-northern Appalachian foreland basin and the Sevier-Paperville formation in the southern Appalachian foreland basin (Stevens and Wright, 1981; Thomas 1991). The Taconian orogeny is considered the principal Paleozoic event that metamorphosed Laurentian rocks of the central and northern Appalachians.

## **ACADIAN OROGENY**

Early to Late Devonian (ca. 420-340 Ma) plate convergence resulted in closure of the Iapetus Ocean and the corresponding accretion of a Middle Ordovician arc terrane (Carolina terrane) to the Laurentian margin (Horton et al., 1989; Osberg et al., 1989). The timing of Carolina terrane deformation has been confirmed by  $^{40}\text{Ar}/^{39}\text{Ar}$  analysis of pseudotachylite from the Gold Hill shear zone (muscovite ca.  $377 \pm 4$  Ma; Lavallee, 2003). Emplacement of the Carolina terrane resulted in thrusting of the Piedmont terrane, further thrusting of elements of the Late Proterozoic to Cambrian Laurentian margin

cratonward over Laurentia, and additional clastic wedge deposition primarily onto the central Appalachian platform margin (Thomas, 1977; Osberg et al., 1989). The Acadian clastic wedge is represented by the Chattanooga Shale (Early Devonian) in the central Appalachian foreland basin and the Catskill delta (Middle to Late Devonian) in the northern Appalachian foreland basin (Thomas, 1991). The Acadian orogeny is not known to have metamorphosed Laurentian rocks of the southern Appalachians (Osberg et al., 1989; Tull, 2002), though it may have been a time of local deformation and magmatism.

### **ALLEGHANIAN OROGENY**

Early Carboniferous to Permian (ca. 340-270 Ma) plate convergence resulted in closure of the Theic-Rheic Ocean and corresponding oblique-dextral collision of Gondwanaland with Laurentia (Secor et al., 1986; Hatcher et al., 1989). It has been suggested that the Uchee terrane, a rifted fragment similar to the Carolina terrane, was also accreted to the Laurentian margin before collision with Gondwanaland (Mueller et al., 2005). Collision with Gondwanaland resulted in thrusting of the Late Proterozoic to Permian Laurentian margin and Piedmont terranes as a composite thrust sheet cratonward over Laurentia (Secor et al., 1986; Hatcher et al., 1989; Hatcher, 2002). This resulted in significant deposition and subsequent deformation of clastic-wedge sediment in the Appalachian foreland basin that prograded cratonward onto the platform from the southern and central Appalachians (Thomas, 1977; Hatcher et al., 1989; Hatcher, 2002). The Alleghanian clastic wedge is represented by the Pottsville Formation (Pennsylvanian) in the southern Appalachian foreland basin (Hatcher et al., 1989; Thomas, 1991). Alleghanian metamorphic effects are pervasive in the eastern Blue Ridge and Piedmont, and have been thoroughly documented in the Talladega Belt.

## **TIMING OF EVENTS**

The record of Ordovician (Taconian) and Devonian (Acadian) tectonics in the Smoky Mountain region of North Carolina and Tennessee and how its extension to the south fits with the Late Devonian-Permian (Acadian-Alleghanian) tectonic history in Alabama and west-central Georgia is important for a more complete understanding of southern Appalachian evolution. There is no consensus among current researchers concerning the timing of western Blue Ridge metamorphism between its southernmost extension and the Great Smoky Mountain region farther to the north.

## **STRATIGRAPHIC CONSTRAINTS**

In the Talladega belt of Alabama, the youngest metamorphosed fossils are Early Mississippian (Tournaisian) *Periastron* plant fossils from the Erin Slate (Gastaldo et al., 1993). The presence of these fossils constrains the age of metamorphism in the Talladega belt-western Blue Ridge to be no older than ~360-350 Ma, Early Mississippian (Tournaisian; based on the time scale of Gradstein et al., 2004).

The foreland-sedimentary sequence (Valley and Ridge) is isoclinally folded and cut by faults related to thrust emplacement of the Talladega belt and western Blue Ridge (Tull and Holm, 2005). The youngest deformed sediments of this sequence are the Pottsville Formation (Hatcher et al., 1989). The Pottsville clastic wedge was deposited in the Appalachian foreland basin during the Alleghanian tectonic event. The Pottsville

Formation stratigraphically constrains the youngest age of deformation for the Talladega belt-western Blue Ridge to ~ 316-303 Ma.

## **RADIOMETRIC CONSTRAINTS**

Kish (1983; 1990) made some conventional K/Ar age determinations for whole rock and mineral samples from the western Blue Ridge in the Tennessee-North Carolina region southwest of the Smoky Mountains. However, these data are generally difficult to interpret due to effects of extraneous argon and heterogeneous-mineral assemblages inherent to whole-rock ages (Kish, 1991).

In the western Blue Ridge of North Carolina and Tennessee,  $^{40}\text{Ar}/^{39}\text{Ar}$  age data for low-grade metamorphic rocks indicate Taconian and Acadian metamorphism (Figure 4). Chlorite-grade rocks record Middle to Late Ordovician metamorphism at 460-440 Ma and biotite-grade rocks record Late Devonian metamorphism at 380-360 Ma (e.g., Connelly and Dallmeyer, 1993). Muscovite from mylonitic rocks record Early Mississippian cooling at 355-330 Ma (e.g., Kunk et al., 2006). Taconian metamorphism in the garnet and staurolite zones of the Smoky Mountains has been confirmed by recent U/Pb TIMS ages of ca. 445-455 Ma for garnet-hosted monazite inclusions (Corrie and Kohn, 2007).

Figure 4: Map from the Smoky Mountain region southwest to the Cohettas of North Georgia, with isograds and a combination of  $^{40}\text{Ar}/^{39}\text{Ar}$  and K/Ar ages (from Connelly and Dallmeyer, 1993).

In the Talladega belt of Alabama,  $^{40}\text{Ar}/^{39}\text{Ar}$  age data indicate Alleghanian metamorphism. The oldest  $^{40}\text{Ar}/^{39}\text{Ar}$  ages for metamorphic muscovite are Middle Mississippian, ca. 329-327 Ma, and for hornblende are also Middle Mississippian, ca. 334-330 Ma (Figures 5; McClellan et al., 2007; Steltenpohl et al., 2005). The oldest  $^{40}\text{Ar}/^{39}\text{Ar}$  ages for white mica are Middle to Late Mississippian, ca. 334-320 Ma (Figure 6; McClellan et al., 2005; McClellan et al., 2007). These radiometric ages imply rapid cooling and constrain the timing of the earliest metamorphism to be no younger than ca. 334-320 Ma, Middle to Late Mississippian. In the Piedmont of Alabama and southwest Georgia, Steltenpohl and Kunk (1993) made some  $^{40}\text{Ar}/^{39}\text{Ar}$  age determinations for hornblende (ca. 347-320 Ma; Mississippian), muscovite (ca. 296-283 Ma; Early Permian), and biotite (ca. 293-276; Early Permian) indicating Alleghanian metamorphism. This combined with stratigraphic constraints clearly indicates Mississippian to Pennsylvanian tectonics dominated the history of this region.

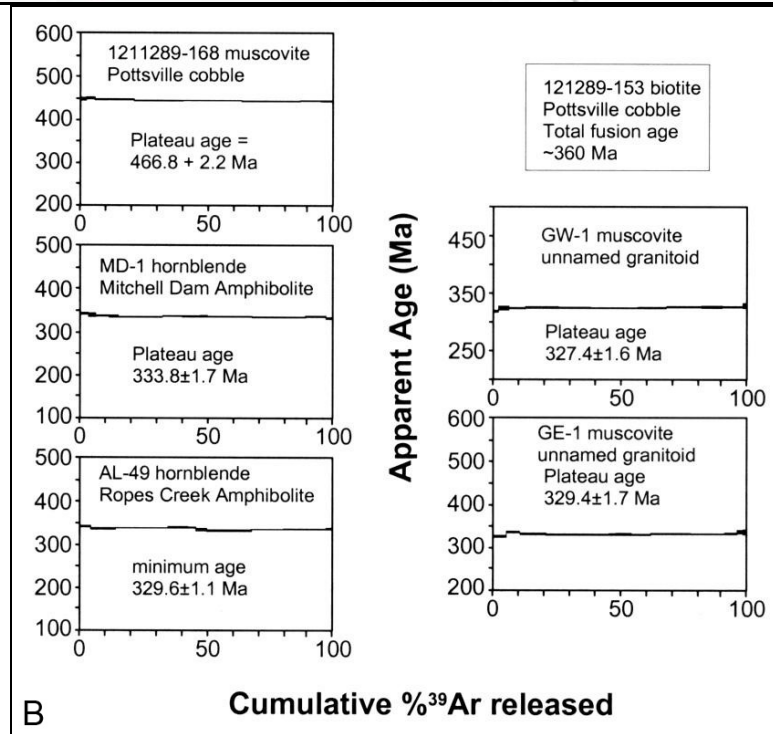

Figure 5: a) Map of the southern Appalachians in Alabama with locations for samples as studied by Steltenpohl et al. (2005). b) Incremental heating spectra and  $^{40}\text{Ar}/^{39}\text{Ar}$  ages for samples reported by Steltenpohl et al. (2005).

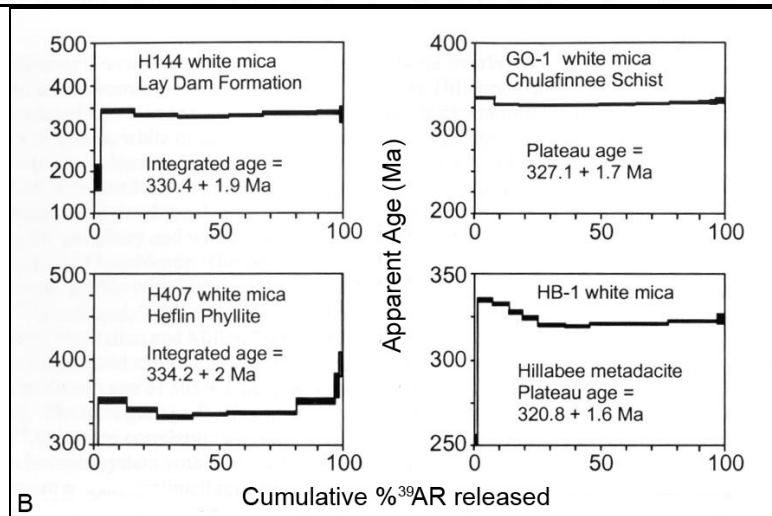

Figure 6: a) Map of the southern Appalachians in Alabama with locations for samples as studied by McClellan et al. (2005). b) Incremental-heating spectra and  $^{40}\text{Ar}/^{39}\text{Ar}$  ages for samples reported by McClellan et al. (2005). Note that the main area for sampling in the present study (see Figure 7) begins in the vicinity of Cartersville, where the Talladega belt tectonic stratigraphy has been correlated with the Blue Ridge stratigraphy by the mapping of Tull and Holm (2005).

## **GIS DATABASE**

A GIS database was constructed in order to manage, interpret, and present the radiometric data generated in this thesis. This database includes sample locations, regional and mesoscopic geologic information, and as much sample characterization (petrography, chemical data, etc.) as is practical. The database is web-enabled, and can potentially be utilized by other researchers (Figure 7).

The web-enabled GIS database was constructed using a desktop computer, Auburn University server space, ARCMAP (ARCGIS 9.1 desktop by ESRI) GIS software, the EasySVG (by Adobe) plug-in for ARCMAP, and FrontPage (by Microsoft) web authoring software. A geologic map of the southern Appalachians was scanned and imported into ARCMAP as the raster basemap of the study area and then geo-referenced to the WGS 1984, geographic-coordinate system. The x-y data, attributes, and hyperlinks for each sample location were entered into ARCMAP in spreadsheet form, added as layers to the basemap, and then converted into shapefiles. HTML webpages were constructed for each sample location using FrontPage. The geo-referenced raster basemap and shapefiles were converted, using the EasySVG plugin, into Scalable Vector Graphics (SVG) format. The SVG map files and hyperlinked HTML webpages were published, using FrontPage, onto Auburn University server space. Installation of the SVGViewer (by Adobe), a web browser plug-in, is needed to access the GIS map on the World Wide Web.

Figure 7: Screen capture of the web-enabled GIS map of study area. The particular basemap used is that of Hatcher et al. (1990). The sampling locations (n=24) shown as black triangles.

Scalable Vector Graphics (SVG) is showing promise as a new XML based graphics standard for internet applications and is the best choice for internet mapping (Duce et al., 2002; Herman & Dardailler, 2002; Ruffle & Richens, 2004). SVG is the W3C (World Wide Web Consortium) mark-up language for vector graphics on the internet and also specifies interactive mechanisms and behavior tools (Carrarat et al., 2003). The high retention of resolution by vector graphics at high zoom levels is an inherent advantage of SVG as well as the facilities to interact with the graphics and assign resolution levels to specific map features or zoom levels (Cecconi & Galanda, 2002). The raster image format has been the standard for mainstream internet mapping, however the image quality of raster graphics is marginal for internet mapping (Cecconi & Galanda, 2002) and the raster format requires large server capacities and lacks interactive abilities (Duce, et al, 2002).

The web-enabled GIS constructed for this thesis can be classified as a “single-source GIS,” meaning it has a single website or server, and sub-classified as dynamic due to the interactive nature of SVG (Shaig, 2001). The functionality of this web-enabled GIS can be classified as a “map server,” defined by Rinner (1998) as being able to provide graphics on the internet as well as interactive tools, or alternatively as a “dynamic map browser” by Plewe (1997).

## DESCRIPTION OF TECTONIC UNITS STUDIED

Muscovite-bearing rocks were collected from several tectonic units of the Talladega belt (Figure 8a) and western Blue Ridge (Figure 8b). Refer to Table 1 for tectonostratigraphy of the formations sampled.

Rocks of the Talladega belt have been biostratigraphically correlated with the Laurentian Ocoee Supergroup and Chilhowee Group of the western Blue Ridge and the Shady Dolomite of the Valley and Ridge (Tull et al., 1988). The Talladega belt includes a lower clastic sequence (1.5 km thick; Kahatchee Mountain Group), conformably overlain by a middle carbonate sequence (1.5 km thick; Sylacauga Marble Group), unconformably overlain by an upper clastic sequence (2-5 km thick; Talladega Group), which is tectonically overlain by a Middle Ordovician volcanic terrane (Hillabee Greenstone; Tull et al., 1982; McClellan et al., 2007). Seven samples were collected from the Lay Dam Formation of the Talladega Group (Table 1). The Lay Dam Formation is a clastic sequence of slates and metasilstones unconformably overlying the Sylacauga Marble Group (Carrington, 1973). The Lay Dam Formation is stratigraphically equivalent to the Mineral Bluff Group in the western Blue Ridge (Tull, 2002; Tull et al., 1988).

The Ocoee Supergroup is the primary rift-basin sequence (300 km long, 75 km wide, and 12 km thick; Hadley, 1970) of the western Blue Ridge and occurs in at least six thrust sheets (Hadley, 1970; Rankin, 1975). The units were originally deposited in a continental rift basin along the eastern Laurentian margin during the Late Proterozoic

Figure 8: Tectonostratigraphic map of the study region: a) Talladega belt of Alabama and Georgia; and b) western Blue Ridge of Georgia and adjacent North Carolina (from Tull and Holm, 2005, their Figure 3b).

(Hatcher, 1989; Tull and Holm, 2005). The Ocoee Supergroup includes the Great Smoky Group overlying the Snowbird Group along the pre-metamorphic Greenbrier fault (King, 1958; Tull et al., 1993). The Snowbird Group consists primarily of highly feldspathic alluvial, fluvial, and shallow marine clastic rocks deposited over Grenville basement (Hatcher, 1989; Tull and Holm, 2005) during a limited cycle of extension associated with continental rifting (Li and Tull, 1998). The Snowbird Group is 4-km thick and had a source area to the east and southeast (King, 1964; Rodgers, 1972). Four samples were collected from the Pinelog Formation of the Snowbird Group (see Table 1). The Great Smoky Group is a thick unit of relatively deep marine sandstone and shale (Hatcher, 1989; Tull and Holm, 2005) and was deposited during a more aggressive cycle of extension (Li and Tull, 1998). The Great Smoky Group is 7-km thick and had a source area to the northeast (King, 1958; Rodgers, 1972). Thirteen samples were collected from several formations of the Great Smoky Group (see Table 1). The Walden Creek Group overlies the Great Smoky Group on the footwall side of the Greenbrier fault (King, 1958; Tull et al., 1993) and is a unit of unstable shelf deposits that could be facies equivalent to the Great Smoky Group or an unrelated sequence of a separate basin (Rankin, 1975). The Walden Creek Group is 2-km thick and had a source area to the northwest (King, 1964; Rodgers, 1972). Three samples were collected from the Wilhite Formation of the Walden Creek Group. The Chilhowee Group, a drift-facies sequence, conformably overlies the Ocoee Supergroup and is relatively widespread (Rankin 1975; Tull et al., 1993). The Chilhowee Group consists of shallow-marine sandstones and shales originally deposited post-rift over the Ocoee Supergroup and Grenville basement highs, during the Early Cambrian (King, 1958; Hatcher, 1989; Tull and Holm, 2005).

Rocks of the Murphy belt lies within the core of a regional isoclinal fold (170 km long, 1300-2000 m thick; Hurst, 1955) and gradationally overlie the Ocoee Supergroup southeast of the Greenbrier fault (Tull et al., 1993). Lithologies of the Murphy belt consist primarily of the drift-facies Hiawasse River Group (Tull et al., 1991) or alternatively the Murphy Belt Group (Thigpen and Hatcher, 2006). The Murphy Belt Group includes the Nantahala and Brasstown Formations and the Murphy Marble (Tull and Holm, 2005) unconformably overlain by the Mineral Bluff Group. The Nantahala and Brasstown Formations conformably overlie the Ocoee Supergroup (Tull and Holm, 2005) and are considered to be outer margin equivalents of the Chilhowee Group (Aylor, 1994). The Murphy Marble conformably overlies the Nantahala and Brasstown Formations (Tull and Holm, 2005) and represents the base of the Cambrian-Ordovician carbonate shelf along the Laurentian margin (Keith, 1907). The Mineral Bluff Group is a clastic sequence of metaconglomerates, metasandstones, and metasiltsstones that are interbedded with metavolcanic units (Tull et al., 1991). Four samples were collected from the Mineral Bluff Group (see Table 1).

## **SAMPLE PETROGRAPHY**

The petrography of minerals - a study of their characteristics including habit, strain state, grain size, and associations in rock assemblages - provides a foundation for interpreting their history. Thus, efforts to date minerals by radioactive decay are best carried out with a characterization that focuses on the phase(s) of interest. Muscovite is a very powerful mineral for the radiometric dating of orogenic events through the K-Ar and  $^{40}\text{Ar}/^{39}\text{Ar}$  method. The bulk closure temperature of muscovite for argon retention ( $350 \pm 50^\circ\text{C}$ ; e.g., Purdy and Jager, 1976) is such that ages from sub-greenschist and lower greenschist facies rocks can approximate the timing of muscovite growth, whereas ages for higher-grade rocks tend to record the timing of cooling. Muscovite is common in metamorphic rocks from a wide range of protoliths. Furthermore, the growth of muscovite can usually be placed in the context of a sample's deformational history and its crystal structure efficiently retains radiogenic gases. The relationship of muscovite grains to fabric development within a rock sample has important implications for interpreting the radiometric data. Muscovite from a rock that has a simple metamorphic history would be expected to yield a single age. Muscovite from a rock that has experienced multiple generations of fabric development would be expected to yield a range of ages, assuming those fabrics developed near the closure interval (Dodson, 1973) for Ar in muscovite. However, if the muscovite was thoroughly recrystallized, thereby overprinting the older fabrics, the radiometric data pertains to the latest metamorphic generation.

Rock samples for this thesis are from four distinct structural settings within the western Blue Ridge. These are the Cartersville transverse zone, the Great Smoky fault, the Ducktown anticlinorium, and the Murphy synclinorium. The four sample groups have unique metamorphic grades, muscovite characters, strain features, and metamorphic fabrics. Petrography for representative samples will first be discussed for the southernmost extent of the western Blue Ridge and then west to east according to structural setting from the thrust front into the center of the belt.

### **CARTERSVILLE TRANSVERSE ZONE**

The Cartersville transverse zone (see Figure 8; as defined by Tull and Holm, 2005) marks stratigraphic and structural contrasts between the Talladega and western Blue Ridge belts. The western Blue Ridge is a thick rift-facies sequence metamorphosed mostly to biotite grade or higher (indicating relatively deep burial) with regional isoclinal folds. The Talladega belt is a relatively thin terrane metamorphosed mostly to biotite grade or lower (indicating relatively shallow burial), with no rift-facies rocks or isoclinal folds. Samples CV-7a, CV-8a, CV-8b, and CV-5a (Figure 9) were collected from the northeast extension of the Talladega belt. Samples CV-3 and CV-2 (Figure 10) were collected from the zone where the Talladega belt trends into the western Blue Ridge. Samples CV-1 and CV-10 (Figure 11) were collected from the southwestern extension of the western Blue Ridge. Refer to Table 2 (Analytical Results chapter) for geographic coordinates.

Figure 9: Photomicrographs of metamorphic textures in rocks from the Talladega belt (scale bars are 1.0 mm; cross-polarized light). (a) Sample CV-7a, biotite-muscovite phyllite. Sample characterized by a single-generation foliation. Muscovite porphyroclasts are aligned with foliation. (b) Sample CV-8a, muscovite phyllite. Sample characterized by an early generation, mica-rich fabric cut by a late-generation quartz and retrograde chlorite (cl) rich fabric. (c) Sample CV-8b, muscovite phyllite. Sample characterized by a single-continuous foliation with abundant retrograde chlorite. (d) Sample CV-5a, muscovite phyllite. Sample characterized by a single-continuous foliation defined by fine-grained muscovite and elongated quartz grains. (e) Map of sample localities (adapted from Tull and Holm, 2005).

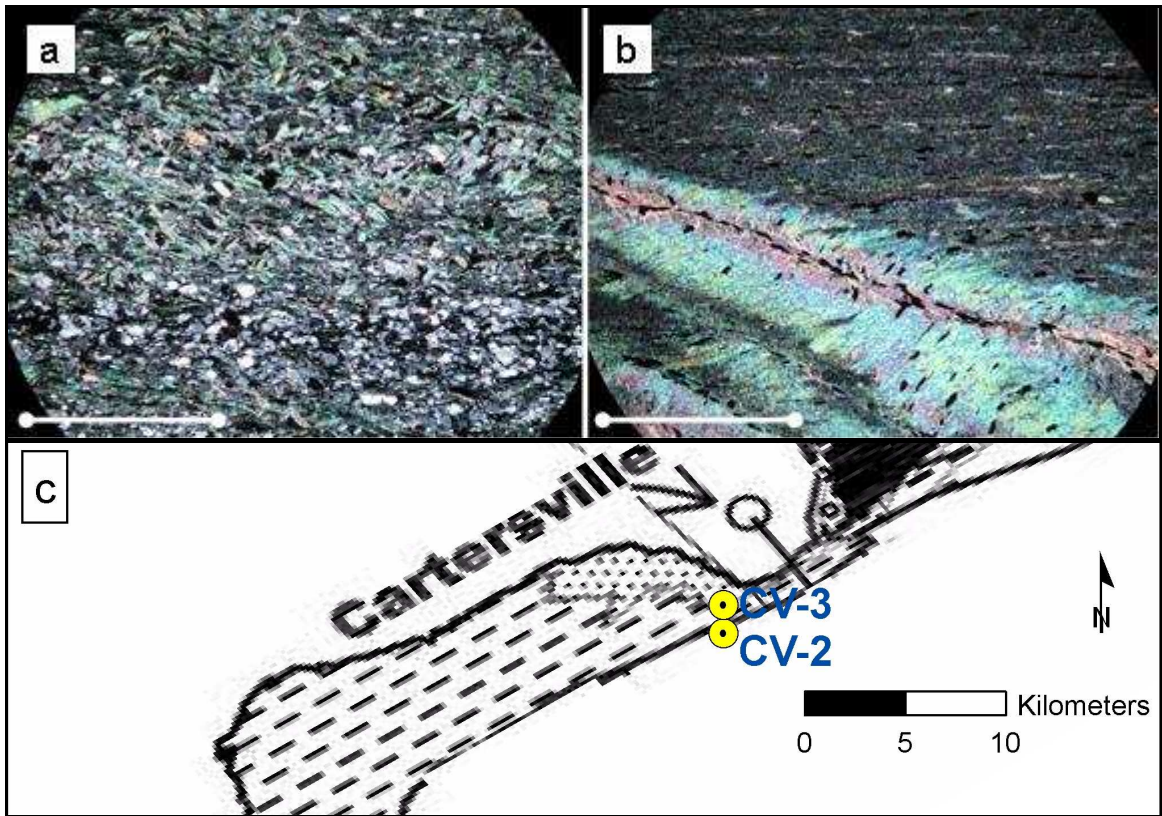

Figure 10: Photomicrographs of metamorphic textures in rocks from the Cartersville transverse zone (scale bars represent 1.0 mm; cross-polarized light). (a) Sample CV-3, muscovite phyllite. Sample characterized by a single generation, spaced foliation. Sample has abundant retrograde chlorite. (b) Sample CV-2, garnet-chlorite-muscovite phyllite. Sample characterized by an early generation, continuous foliation cut by late-stage crenulation. (c) Map of sample localities (adapted from Tull and Holm, 2005).

Figure 11: Photomicrographs of metamorphic textures in rocks from the western Blue Ridge-Cartersville transverse zone (scale bars represent 1.0 mm; cross-polarized light). (a) Sample CV-1, muscovite phyllite. Sample characterized by a single generation, spaced foliation and abundant feldspar porphyroclasts. (b) Sample CV-10, muscovite schist. Sample characterized by an early generation, spaced foliation deformed by late-stage fabric development (as evidenced by muscovite porphyroclasts). (c) Map of sample localities (adapted from Tull and Holm, 2005).

Sample CV-7a (Figure 9a) is a biotite-muscovite phyllite of the Lay Dam Formation (alternatively the Mineral Bluff Group of the western Blue Ridge). The sample is characterized by a single-generation fabric, defined by fine-grained muscovite and minor biotite. Muscovite porphyroclasts could be detrital grains or relicts of an earlier generation. Samples CV-8a and CV-8b (Figures 9b and 9c respectively) are muscovite phyllites of the Lay Dam Formation. Sample CV-8a is characterized by a multiple-generation fabric. The early-generation foliation is defined by fine-grained muscovite and chlorite. Late-stage foliation is defined by coarser grained muscovite and abundant retrograde chlorite. The quartz grains are strained as evidenced by undulose extinction. The sample is graphitic and has hematite staining. Sample CV-8b is characterized by a single-generation fabric, defined by very fine-grained muscovite. An abundance of retrograde chlorite is present. Sample CV-5a (Figure 9d) is a muscovite phyllite of the Lay Dam Formation. The sample is characterized by a single-generation fabric, defined by fine-grained muscovite and elongated quartz grains. Undulose extinction, exhibited by the quartz grains, indicates strain.

Sample CV-3 (Figure 10a) is a muscovite phyllite of the Dean Formation, Great Smoky Group. The sample is characterized by two planar fabrics. Early-generation spaced cleavage is defined by fine-grained muscovite. Late-stage deformation has sheared the early foliation. Quartz grains are strained as evidenced by undulose extinction. The sample is predominantly quartz and has abundant retrograde chlorite. Sample CV-2 (Figure 10b) is a garnet-chlorite-muscovite phyllite of the Otto Formation (eastern Blue Ridge). The sample is characterized by a multiple-generation fabric. The early generation, continuous foliation is defined by fine-grained muscovite and chlorite.

Late-stage deformation has crenulated the early foliation. The sample is graphitic and has abundant garnet porphyroblasts. Strain is indicated in the quartz grains by undulose extinction.

Sample CV-1 (Figure 11a) is a muscovite phyllite of the Wilhite Formation, Walden Creek Group. The sample is characterized by a single-generation spaced foliation, defined by fine-grained muscovite. The sample is graphitic and has abundant feldspar porphyroclasts. The quartz and feldspar grains are strained as evidenced by undulose extinction. Sample CV-10 (Figure 11b) is a muscovite schist of the Wilhite Formation. The sample is characterized by a multiple-generation fabric. The early-spaced foliation is defined by fine-grained muscovite. Late-stage deformation crushed the early foliation forming muscovite porphyroclasts. Strain is evident in quartz grains by the exhibition of undulose extinction.

## **GREAT SMOKY FAULT**

The Great Smoky fault is the northwestern most structure of the western Blue Ridge. This region of the western Blue Ridge is characterized by sub-greenschist facies, metasedimentary rocks. Samples WM-9a (Figure 12a) and WM-9c (Figure 12b) were collected near the Carters Lake Dam, approximately 2000 ft. due north of the stop localities indicated in McConnell (1986). Sample WM-10 (Figure 12c) was collected farther north, near Chatsworth along Route 52 (refer to Table 2 for geographic coordinates).

Samples WM-9a and WM-9c are graphitic-muscovite metasilstones of the Ammons Formation, Great Smoky Group. Both samples have abundant clasts of relict quartz pebbles. These quartz clasts are strongly strained, as evidenced by undulose

Figure 12: Photomicrographs of metamorphic textures in rocks from the Great Smoky fault (scale bars represent 1.0 mm; cross-polarized light). (a) Sample WM-9a, graphitic-muscovite metasiltstone. Sample characterized by a multiple-generation fabric, plastic deformation of quartz, brittle deformation of micas, and large relict-quartz pebbles or clasts (qp). (b) Sample WM-9c, graphitic-muscovite metasiltstone. Sample has similar fabric with a relatively higher abundance of feldspar clasts (fe) and coarser grained mica. (c) Sample WM-10, muscovite phyllite. Sample characterized by an anastomosing, multiple-generation fabric defined by relatively fine-grained muscovite and relict apatite (ap) clasts. (d) Map of sample localities (adapted from Tull and Holm, 2005).

extinction and subgrains, and are surrounded by recrystallized quartz grains with interlobate boundaries. The mica is characterized by fine-grained muscovite recrystallized from the original sedimentary matrix. These samples have apparently experienced multiple generations of fabric development, with ductile deformation of quartz and brittle deformation of micas. Radiometric data for these samples may be influenced by the presence detrital minerals. Sample WM-10 is a muscovite phyllite of the Pinelog Formation, Snowbird Group. Foliations are defined by very fine-grained muscovite with an anastomosing multiple-generation fabric. The sample is also characterized by an abundance of apatite clasts.

## **DUCKTOWN ANTICLINORIUM**

The Ducktown anticlinorium is a northeast-trending synmetamorphic fold east of the Great Smoky fault. This regional antiform is characterized, as discussed by Hatcher and Goldberg (1991), by a core of staurolite-grade rocks (amphibolite facies) with limbs of garnet and biotite-grade rocks (upper-greenschist facies). Samples BB-1 (Figure 13a) and BB-2 (Figure 13b) were collected from a tailings pile at the Bura Bura Mine in Ducktown. Samples MS-2 (Figure 13c) and MS-3 (Figure 13d) were collected farther east along Route 64 (refer to Table 2 for geographic coordinates).

Samples BB-1 and BB-2 are garnet-biotite-muscovite schists of the Copperhill Formation, Great Smoky Group. The samples are characterized by a multiple-generation fabric, an abundance of garnet porphyroblasts, and crystal-plastically deformed quartz grains as evidenced by undulose extinction and subgrains. An early-generation foliation is defined by coarse muscovite and biotite grains. Late-stage deformation has crenulated the foliation in sample BB-1. Late-stage folding deformed the foliation in sample BB-2.

Figure 13: Photomicrographs of metamorphic textures in rocks from the Ducktown anticlinorium (scale bars represent 1.0 mm; cross-polarized light). These garnet-biotite-muscovite schists are characterized by an early-generation foliation, defined by coarse-grained muscovite (mu) and biotite (bi), subsequently deformed by late-stage folds. (a) Sample BB-1. (b) Sample BB-2. (c) Sample MS-2. (d) Sample MS-3. (e) Map of sample localities (adapted from Tull and Holm, 2005).

Sample BB-2 also has minor retrograde chlorite. Sample MS-2 is a garnet-biotite-muscovite schist of the Copperhill Formation. An early-generation foliation is defined by coarse-grained muscovite and biotite. The sample has abundant garnet porphyroblasts. Some quartz grains have recrystallized and some are older-strained grains. Late-stage deformation has crenulated the foliation. Sample MS-3 is a garnet-biotite-muscovite schist of the Upper Anakeesta-Wehuttu Formations, Great Smoky Group. An early-generation foliation is defined by coarse muscovite and biotite grains. The biotite grains were subsequently deformed, indicating post-growth shear, as evidenced by lens shaped porphyroclasts and kink bands.

## **MURPHY SYNCLINORIUM**

The Murphy synclinorium is a northeast-trending synmetamorphic fold east of the Ducktown anticlinorium. This regional synform, as discussed by Hatcher and Goldberg (1991), has a core of chlorite-grade rocks (lower-greenschist facies) with limbs of biotite and garnet-grade rocks (upper-greenschist facies). Samples MS-5, 6, 7, and 8 (Figure 14) were collected from the core of the synclinorium along Route 64 (refer to Table 2 for geographic coordinates).

Sample MS-5 (Figure 14a) is a chlorite-muscovite phyllite of the Mineral Bluff Group. The sample is characterized by fine-grained muscovite and chlorite that define an early-generation foliation. Quartz grains consist of recrystallized and strained-host grains. Late-stage deformation has sheared the foliation. Sample MS-6 (Figure 14b) is a chlorite-muscovite phyllite of the Mineral Bluff Group. An early foliation, rich in quartz and chlorite, is deformed and rotated by a later formed foliation, defined by fine-grained muscovite. The quartz grains consist of recrystallized and older-strained grains. Sample

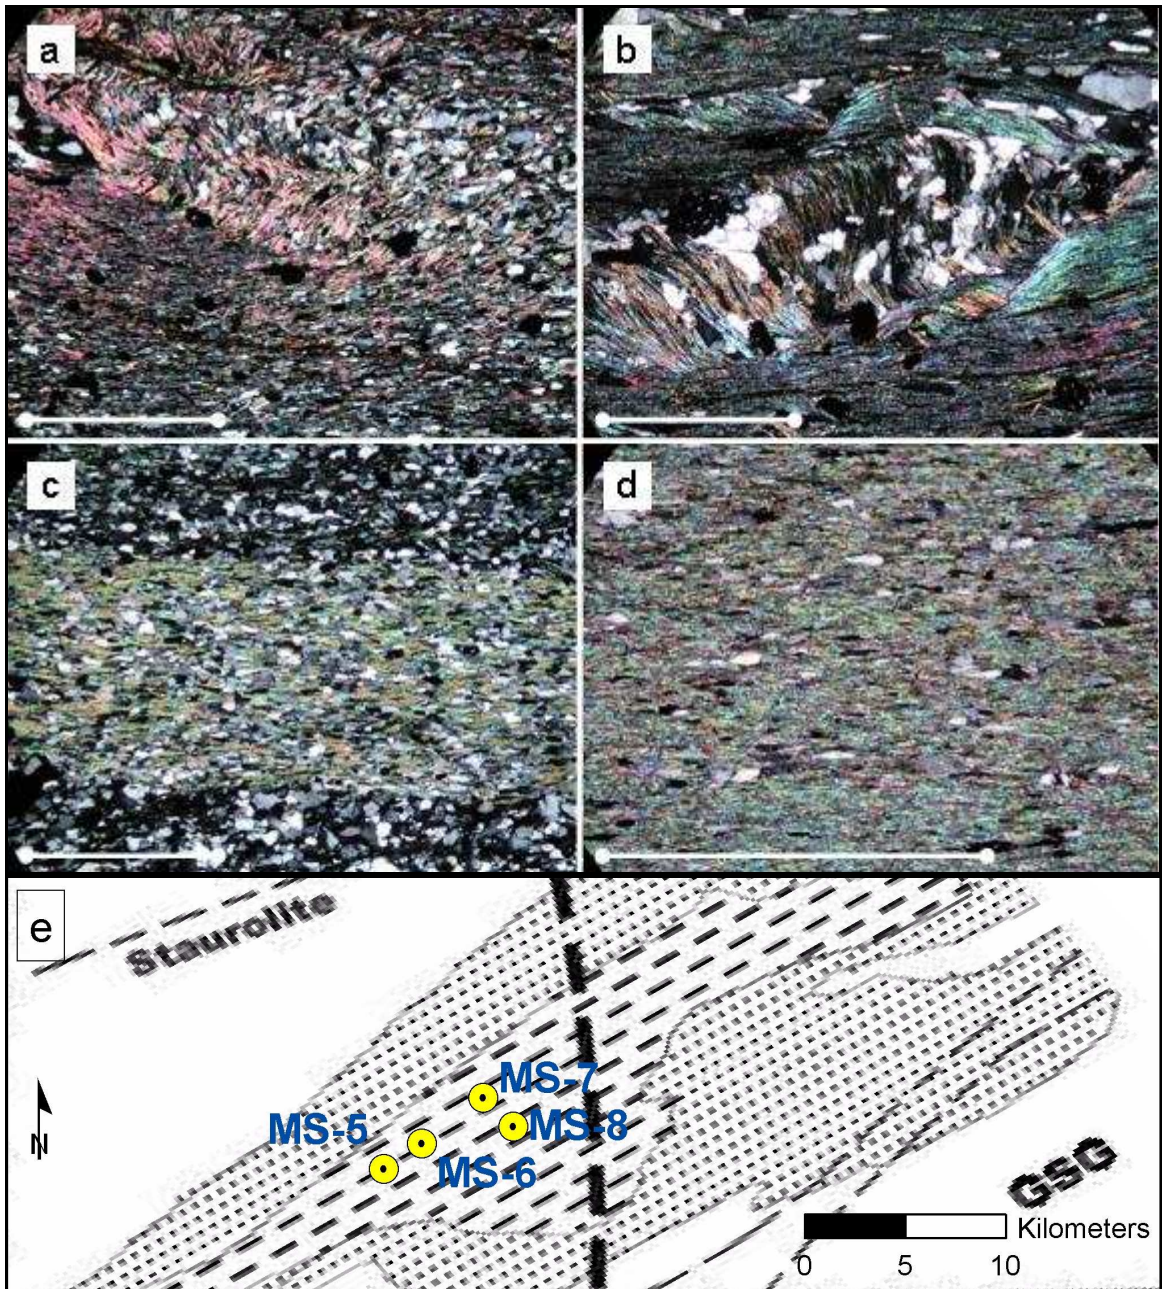

Figure 14: Photomicrographs of metamorphic textures in rocks from the Murphy synclinorium (scale bars = 1.0 mm; cross-polarized light). (a) Sample MS-5, chlorite-muscovite phyllite. Sample characterized by an early-generation planar fabric defined by muscovite sheared by late-stage deformation. (b) Sample MS-6, chlorite-muscovite phyllite. Sample characterized by an early-generation, quartz-rich, fabric rotated by a late-generation, mica-rich, fabric. (c) Sample MS-7, chlorite-muscovite phyllite or slate. Sample characterized by undeformed and fine-grained muscovite laths that define a single cleavage. (d) Sample MS-8, chlorite muscovite slate. Sample characterized by a continuous foliation defined by very finely-grained muscovite and elongated quartz grains. (e) Map of sample localities (adapted from Tull and Holm, 2005).

MS-7 (Figure 14c) is a chlorite-muscovite phyllite of the Mineral Bluff Group. The sample has a single continuous cleavage (phyllitic or slaty) defined by undeformed and fine-grained muscovite laths. The general lack of microstructural evidence for intracrystalline strain in quartz indicates annealing. Sample MS-8 (Figure 14d) is a chlorite-muscovite slate of the Mineral Bluff Group. The sample is characterized by very-fine grained muscovite and elongated quartz grains that define a continuous slaty cleavage. This sample also lacks evidence for intracrystalline strain.

## <sup>40</sup>Ar/<sup>39</sup>Ar ANALYSIS

### BASIS OF THE METHOD

Argon is a noble gas that occurs naturally throughout the atmosphere and potassium is a common element in rock-forming minerals. Several isotopes of these elements pertain to the K/Ar method and <sup>40</sup>Ar/<sup>39</sup>Ar technique (Figure 15). <sup>40</sup>Ar occurs naturally and is produced by a radioactive-decay branch of <sup>40</sup>K, due to electron-capture and positron-emission pathways (Faure, 1986). <sup>39</sup>Ar is produced entirely by the decay of <sup>39</sup>K and <sup>42</sup>Ca, <sup>38</sup>Ar occurs naturally and is produced by the radioactive decay of <sup>38</sup>Cl, <sup>37</sup>Ar is produced entirely by the radioactive decay of <sup>40</sup>Ca, and <sup>36</sup>Ar occurs naturally and is produced by the radioactive decay of <sup>40</sup>Ca (Dickin; 1995). The naturally occurring <sup>40</sup>Ar/<sup>36</sup>Ar ratio in the atmosphere is 295.5, enabling the correction for atmospheric <sup>40</sup>Ar (Faure, 1986).

The K/Ar method has conventionally been used to date K bearing minerals. Two separate aliquots of <sup>40</sup>K and radiogenic <sup>40</sup>Ar are measured quantitatively, <sup>40</sup>Ar\* in an inert-gas mass spectrometer and <sup>40</sup>K by flame photometry or one of several chemical methods. The fundamental-age equation (as derived in Dalrymple & Lanphere, 1969) is

$$t = (1/\lambda) \ln (^{40}\text{Ar}^* / ^{40}\text{K} + 1).$$

The decay constant ( $\lambda$ ) for <sup>40</sup>K → <sup>40</sup>Ar (as described in McDougall & Harrison, 1999) is 5.543\*10<sup>-10</sup>/year.

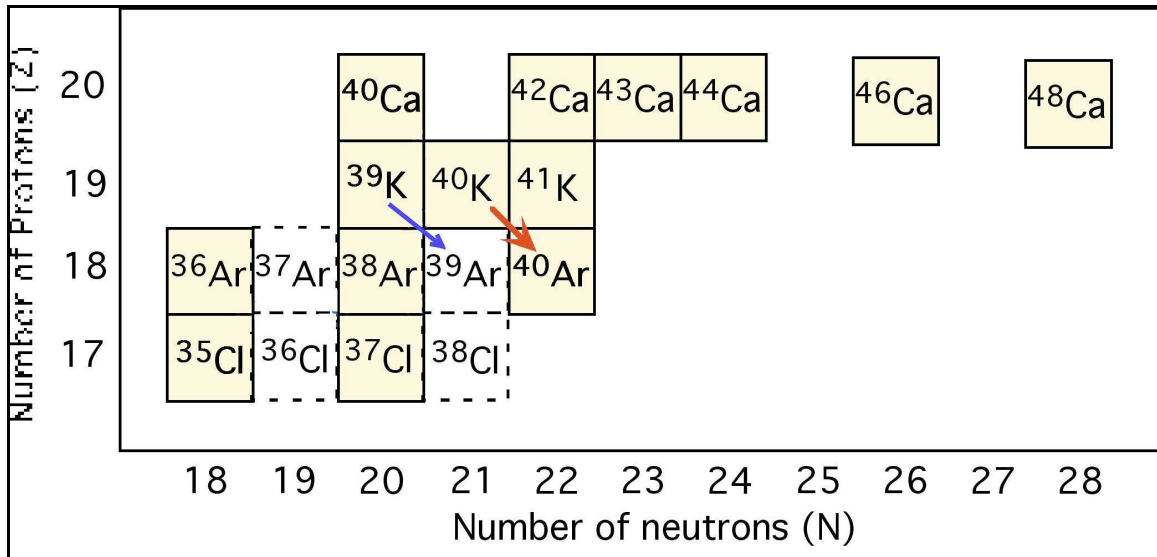

Figure 15: Decay scheme and isotopes relevant to the  $^{40}\text{Ar}/^{39}\text{Ar}$  method. Symbols filled with yellow signify naturally-occurring isotopes. Red arrow signifies the  $^{40}\text{K} \rightarrow ^{40}\text{Ar}^*$  decay reaction that occurs in nature. The blue arrow signifies the  $^{39}\text{K}(n,p)^{39}\text{Ar}_K$  reaction that occurs in a nuclear reactor and enables the  $^{40}\text{Ar}/^{39}\text{Ar}$  method.

#### $^{40}\text{Ar}/^{39}\text{Ar}$ DATING TECHNIQUES

The  $^{40}\text{Ar}/^{39}\text{Ar}$  technique is a variation of K/Ar. Based on the assumption that the  $^{39}\text{K}/^{40}\text{K}$  ratio is constant in nature and  $^{39}\text{Ar}_K$  is dependent upon the  $^{39}\text{K}$  in the sample,  $^{40}\text{Ar}^*/^{39}\text{Ar}_K$  is proportional to  $^{40}\text{K}/^{40}\text{Ar}^*$  and  $^{39}\text{Ar}_K$  can be substituted for  $^{40}\text{K}$  (McDougall & Harrison, 1999). The age equation (as discussed in McDougall and Harrison, 1999) is:

$$t = (1/\lambda) \ln(^{40}\text{Ar}^*/^{39}\text{Ar}_K(J)+1).$$

$^{40}\text{Ar}^*$  is the fraction of  $^{40}\text{Ar}$  produced by radioactive decay.  $^{39}\text{Ar}_K$  is the  $^{39}\text{Ar}$  produced through neutron-capture, proton-emission reactions by bombardment with fast, high energy neutrons in a nuclear reactor (Merrihue and Turner, 1966). Determination of the production factor (J; as discussed in Dalrymple et al., 1981) for the  $^{39}\text{K} \rightarrow ^{39}\text{Ar}$  reaction, in the mineral sample and corresponding monitor of known age, during irradiation is

$$J = e^{\lambda t} - 1 * 1 / (^{40}\text{Ar}/^{39}\text{Ar}).$$

The  $^{40}\text{Ar}/^{39}\text{Ar}$  technique permits precise age determinations on smaller sample sizes (such as single crystals) and allows for simpler data acquisition, as the isotopic ratio data are collected with a single measurement instead of quantitatively analyzing two separate aliquots. This reduces the standard error and lab time for radiometric analysis relative to K/Ar.

The closure temperature (see Petrography section) for any mineral is variable and heavily dependant upon cooling rate and grain size. The cooling of geologic temperature through time (Figure 16a) influences the closure temperature for muscovite. A low cooling rate favors a cooler closure temperature and a high cooling rate favors a higher closure temperature. This influences the ratio of  $^{40}\text{Ar}/^{40}\text{K}$  through geologic time (Figure 16b). Before the closure temperature is reached there is no retention of daughter ( $^{40}\text{Ar}$ ) atoms. Cooling through an interval of partial retention of daughter atoms (the “closure interval”; Dodson, 1973) is shorter for fast cooling rates and longer for slow cooling rates. After muscovite cools through its closure temperature there is complete retention of daughter atoms within the crystal lattice (Giletti; 1972). The grain size of micas also influences the closure temperature (Hames and Bowring, 1994). A smaller muscovite-grain size favors a cooler closure temperature due to the short diffusion dimension and a larger grain size favors a hotter closure temperature due to its longer diffusion dimension. These variables must be considered for reliable interpretation of radiogenic data. In this study the cooling rate of geologic temperature is assumed to be  $5^{\circ}\text{C}/\text{m.y.}$  and the grain size varies between 0.1mm to 0.5 mm (Figure 17). Given the grain size variation, the range of closure temperatures may have varied by as much as  $50^{\circ}\text{C}$ . Given the  $5^{\circ}\text{C}/\text{m.y.}$  cooling rate, the timing of the retention of argon may have a 10 m.y. variation.

Figure 16: Idealized closure-temperature concept (figure adapted from Dodson, 1973):  $T_0$  = initial temperature,  $T_c$  = closure temperature, c = argon retention at diffusion-domain centers (crystal cores), e = argon retention throughout diffusion domains; a) Plots geologic temperature against geologic-cooling history (time). b) Plots the daughter/parent ratio ( $^{40}\text{Ar}/^{40}\text{K}$ ) against geologic time.

Figure 17: Closure temperature for muscovite grain sizes in this study as a function of geologic-cooling rate (calculated with the model of Dodson, 1973, with muscovite-diffusion parameters from Hames and Bowring, 1994).

## ANALYTICAL METHODS

Samples were selected on the basis of structural setting and petrography. Low-grade metamorphic rocks containing muscovite were collected from the Cartersville transverse zone, the Blue Ridge thrust region, and a transect from the Ducktown anticlinorium into the Murphy synclinorium (refer to Table 2). The samples were gently crushed with mortar and pestle, separated into size fractions using standard test sieves, and examined under binocular microscope. Approximately 50 grains of muscovite and biotite (if present) were picked from each sample, immersed in ethanol and stored in centrifuge vials. The mica grains were packaged in aluminum foil along with aliquots of a monitor mineral (Fish Canyon Sanadine; ca. 28.04 Ma; Renne et al, 1998). The sample package was sent to the McMaster University nuclear reactor in Hamilton, Ontario for neutron irradiation.

The mica grains and monitors were analyzed at the Auburn Noble Isotope Mass Analysis Laboratory (ANIMAL; Figures 18 and 19), a facility under the direction of Dr. Hames of the Auburn University Department of Geology and Geography. The lab is set up for single crystal, isotopic analysis utilizing the  $^{40}\text{Ar}/^{39}\text{Ar}$  technique and provides enhanced sensitivity and resolution relative to labs that use bulk sample methods. Single crystals of a single mineral were analyzed individually. This minimizes effects due to extraneous argon and heterogeneous-mineral assemblages inherent to multigrain analysis.

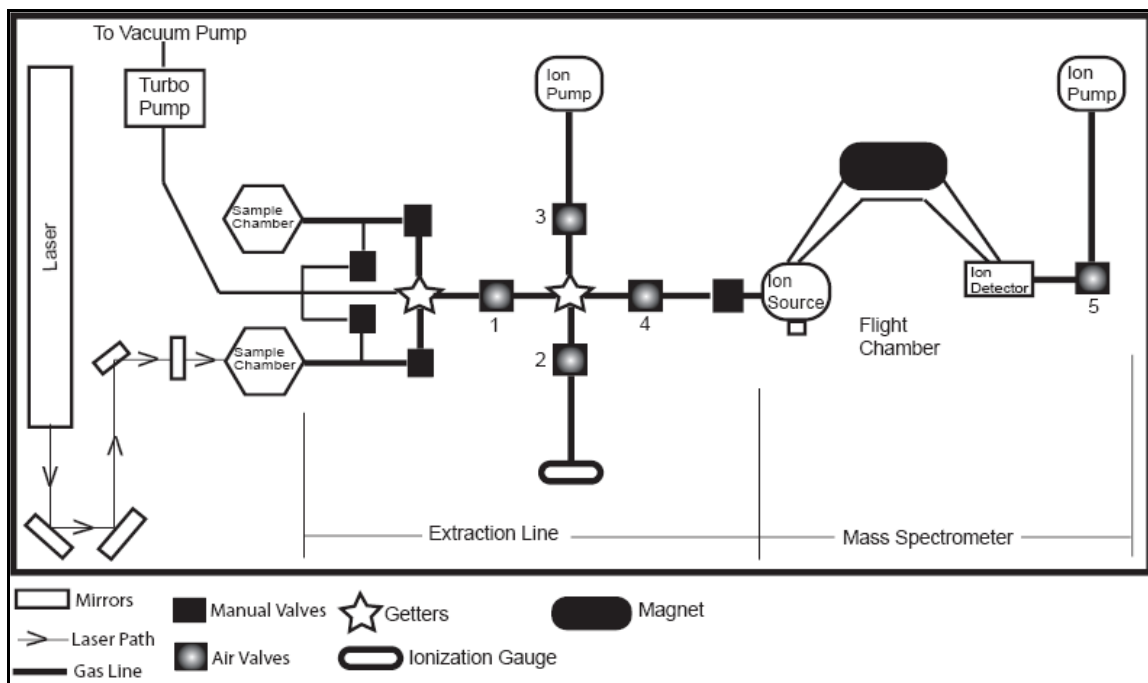

Figure 18: Schematic diagram of the lab apparatus in the Auburn Noble Isotope Mass Analysis Laboratory (ANIMAL facility).

Figure 19: The author analyzing samples in the Auburn Noble Isotope Mass Analysis Laboratory (ANIMAL facility).

The laboratory is equipped with an ultra-high vacuum, 90-degree sector, 10-cm radius spectrometer optimized for single-crystal  $^{40}\text{Ar}/^{39}\text{Ar}$  research. The spectrometer employs second-order focusing (Cross, 1951), and is fitted with a high sensitivity electron-impact source and a single ETP electron multiplier (with signal amplification through a standard pre-amplifier). The total volume of the spectrometer is 400 cc. Resolution in the instrument (with fixed slits for the source and detector) is constrained to  $\sim 150$ . The high sensitivity and low blank of the instrument permits measurement of  $10^{-14}$  mole samples to within 0.3% precision. The extraction line is fitted with a 50W Synrad  $\text{CO}_2$  IR laser for heating and fusing silicate minerals and glasses. The sample chamber uses a Cu planchet, KBr cover slips, and low-blank UHV ZnS window (manufactured at Auburn University and based on the design of Cox et al., 2003). The laser system is suitable for fusion analysis of single crystals as employed in this study. The laser beam delivery system utilizes movable optical mounts and a fixed sample chamber to further minimize volume and improve conductance of the extraction line. The extraction line for this system is fully computer automated and utilizes a combination of Varian and Nupro pneumatic valves, and Varian turbomolecular and ion pumps. Residual and sample reactive gases are pumped out of the line through use of SAES AP-10 non-evaporable getters. Pressures in the spectrometer and extraction line are routinely below  $\sim 5 \times 10^{-9}$  torr, as measured with an ionization gauge. An automated pipette delivers standard aliquots for use in measuring sensitivity and mass fractionation. The time required to inlet or equilibrate a 'half-split' of a sample is less than 7 seconds, and the inlet time for a full sample is 20 seconds. Typical blanks for the entire system (4 minute getting time, while running sanidine monitor minerals) in May of 2006 are as follows (in moles):  $^{40}\text{Ar}$ ,

$2.1 \times 10^{-16}$ ;  $^{39}\text{Ar}$ ,  $1.6 \times 10^{-17}$ ;  $^{38}\text{Ar}$ ,  $3.2 \times 10^{-18}$ ;  $^{37}\text{Ar}$ ,  $2.6 \times 10^{-18}$ ;  $^{36}\text{Ar}$ ,  $1.7 \times 10^{-18}$ . Computer control of the laser, laser optics, extraction line, mass spectrometer, and data recording is enabled with National Instruments hardware and the Labview programming environment. Initial data reduction is accomplished through an in-house Excel spreadsheet, with final reduction using Isoplot (Ludwig, 2003).

$^{40}\text{Ar}/^{39}\text{Ar}$  isotopic analyses of the irradiated samples were performed to determine their cooling-crystallization ages. The mica grains were individually arranged in a copper planchet and placed in a vacuum sealed chamber. To determine the background levels of gas in the system, blanks were run before sample analyses and after every fifth sample. Air analyses were run daily to confirm the mass spectrometer yields the  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio of 295.5. Argon was extracted from the mica grains by fusing individual crystals with single laser shots. Hydrocarbon contaminants or other active gases that may have been present were removed by gettering the gas. The gas samples were then passed through the ion source and analyzed in the gas mass spectrometer, measuring the individual voltage for  $^{36}\text{Ar}$ ,  $^{37}\text{Ar}$ ,  $^{38}\text{Ar}$ ,  $^{39}\text{Ar}$ , and  $^{40}\text{Ar}$ . The argon isotopic ratio data was then reduced; corrections were made for background gases and interfering isotopes and ages were calculated for the  $^{40}\text{Ar}^*/^{39}\text{Ar}_K$  ratios along with corresponding standard error and deviation (as discussed in McDougall and Harrison, 1999).

## ANALYTICAL RESULTS

Radiometric age determinations included the systematic laser analysis of single muscovite crystals. The data are reported as the mean and standard error at the 68% confidence level ( $\pm 1\text{s}$ ) of approximately ten analyses for each sample or as a range of single-crystal ages (Table 2). Resulting  $^{40}\text{Ar}/^{39}\text{Ar}$  single-crystal ages vary from  $307.1\pm 8.5$  Ma to  $667.0\pm 3.9$  Ma, the younger samples having single mode distributions and the older samples having multiple modes. Younger ages are recorded in muscovite from the Cartersville-thrust region and to the north are represented as younger modes in a more complex record. The oldest ages are recorded for muscovite proximal to the Great Smoky fault, with no single-crystal ages younger than 355 Ma. The overall pattern is a predominance of ages close to 330 Ma for the southern (Cartersville) portion of the Talladega belt-western Blue Ridge, significantly older ages to the north along the Great Smoky fault varying from 355 - 667 Ma (possibly influenced by extraneous argon or a relict/detrital component), and ages varying between 328-465 Ma from along the Ducktown-Murphy transect. The radiometric data will first be discussed for the twelve samples from the Cartersville transverse zone, then for the eleven samples from along the Great Smoky fault, and then west to east for the nine samples across the Ducktown and Murphy structures.

Table 2:  $^{40}\text{Ar}/^{39}\text{Ar}$  data for western Blue Ridge muscovite (SCTF is Single Crystal Total Fusion; n is number of analyses; \* Ages (Ma) quoted as a mean at  $1\sigma$  or as a range).

## CARTERSVILLE TRANSVERSE ZONE

Laser  $^{40}\text{Ar}/^{39}\text{Ar}$  analysis of twelve samples from the Cartersville-thrust region (Figure 20 and Appendix 2) yield single crystal total fusion ages with means that range between  $321.4\pm 4.0$  Ma and  $335.5\pm 0.8$  Ma. Probability distributions and isotope-correlation diagrams (Figures 21 and 22) are presented first for samples collected from the northeast extension of the Talladega Belt. Figures 23 and 24 present the results for samples collected from the zone where the Lay Dam Formation has been correlated along strike into the western Blue Ridge (Tull and Holm, 2005). In general, each sample tends to yield single-crystal ages that are normally distributed, and thus a mean age and standard error of the mean are reported for each. There is no systematic variation among mean ages for samples of the Lay Dam Formation across the Cartersville transverse zone from the Talladega belt into the western Blue Ridge.

A few samples yielded a crystal with an age significantly younger than the mean (CV8a, CV8b, CV6, and CV10). Samples CV6 and CV8a are phyllites of the Lay Dam Formation. CV8b was collected from a boudinaged quartz vein and its age is best expressed as a range (322-341 Ma; Figure 21g). Sample CV10, a schist from the Wilhite Formation, yielded one crystal with an age somewhat younger than the mean ( $325\pm 1$  Ma; Figure 24d). The younger single-crystal ages among these samples could correspond with crystals that had higher defect density or smaller size, and thus lower closure temperature than typical of the group.

Samples CV1 and CV5a, phyllites from the Lay Dam Formation, yielded a few single-crystal ages significantly older than the respective means (Figures 22 and 23). The older single-crystal ages among these samples could be the result of a small proportion of

older muscovite, that could be due to incorporation of detrital minerals or muscovite from an earlier episode of metamorphism.

## GREAT SMOKY FAULT

Seven samples collected from the vicinity of the Cartersville-Great Smoky fault in the western Blue Ridge (Figure 25 and Appendix 2) yield mean  $^{40}\text{Ar}/^{39}\text{Ar}$  ages that vary between  $315.5\pm 0.5$  Ma and  $351.1\pm 1.7$  Ma. Five of these samples tend to yield single-crystal ages that are normally distributed, and thus a mean age and standard error of the mean are reported for each. Figures 26 and 27 present the results for samples collected from various formations of the Ocoee Supergroup, west of the Murphy synclinorium and north of the Cartersville transverse zone. Sample WM2, a phyllite of the Wilhite Formation, yielded the youngest mean age ( $315.5\pm 0.5$  Ma; Figure 26c) of all samples in this study and may be due to a locally-younger zone of deformation. Sample WM6, a phyllite of the Great Smoky Group, yielded a mean age of  $351.1\pm 1.7$  (Figure 27c) somewhat older than other samples in this region and could be the result of slow cooling from an earlier event. Two samples yielded some crystals with a relatively complex distribution (WM3, WM4). Sample WM3 is a schist of the Pinelog Formation and its single-crystal ages are best expressed as a range from 325-345 Ma (Figure 26e). Also, sample WM4, a phyllite of the Pinelog Formation, yields ages ranging from 334-370 Ma (Figure 26g). The notably wide variation in ages among crystals in samples WM3 and WM4 could be due to polymetamorphism or perhaps the influence of detrital minerals.

Figure 25: Geologic map of the Cartersville-Great Smoky fault and locations for samples represented in Figures 26-27 (adapted from Tull and Holm, 2005).

Figure 26: Inverse-isochron and age-probability plots for argon-isotopic data of Cartersville-Great Smoky fault samples WM1a (a-b), WM2 (c-d), WM3 (e-f), and WM4 (g-h) (data-point error crosses are  $1\sigma$ ).

Figure 27: Inverse-isochron and age-probability plots for argon-isotopic data of Cartersville-Great Smoky fault samples WM5 (a-b), WM6 (c-d), and WM7a (e-f) (data-point error crosses are  $1\sigma$ ).

Farther north, four samples from the vicinity of the Cartersville-Great Smoky thrust front in the western Blue Ridge (Figures 28 and 29, and Appendix 2) yield complex distributions of single-crystal ages, and thus an age range is reported for each. The minimum ages are as young as ~355 Ma, however ages older than any plausible timing of Paleozoic metamorphism are also present. Samples WM9a, 9b, and 9c are metasiltsstones from the Ammons Formation and were collected proximal to the fault (WM9c directly from the fault zone). Sample WM10 is a phyllite from the Pinelog Formation collected proximal to the Fort Mountain culmination. The age variation among the crystals in these rocks could be due to polymetamorphism, brittle deformation effects that may have introduced extraneous argon, or influence by detrital minerals.

Figure 28: Geologic map of the Great Smoky fault and locations for samples represented in Figure 29 (adapted from Tull and Holm, 2005).

Figure 29: Inverse-isochron and age-probability plots for argon-isotopic data of Carter Lake samples WM9a (a-b), WM9b (c-d), WM9c (e-f), and Chatsworth sample WM10 (g-h) (data-point error crosses are  $1\sigma$ ).

## **DUCKTOWN-MURPHY TRANSECT**

Nine samples collected along U.S. Hwy. 64 between Ducktown, Tennessee and Murphy, North Carolina in the western Blue Ridge (Figure 30 and Appendix 2) yielded single-crystal  $^{40}\text{Ar}/^{39}\text{Ar}$  ages varying between  $327.9\pm 2.6$  Ma to  $465.5\pm 6.6$  Ma. The samples of the Ocoee Supergroup (BB1, BB2, MS2, MS3, and MS4b) tend to yield complex single-crystal age distributions and the samples of the Mineral Bluff Group (MS5, MS6, MS7, and MS8) tend to yield normally distributed single-crystal ages (Figures 31-33). Sample MS2, a metasandstone of the Copperhill Formation in the Ducktown anticlinorium, is an exception as it yielded normally distributed single-crystal ages with one crystal somewhat older than the mean ( $345\pm 1$  Ma; Figure 31e). Samples MS5 and MS7, phyllites of the Mineral Bluff Group in the Murphy synclinorium, both yielded a crystal with an age significantly older than the mean (Figure 32e and 33c).

## **INTERPRETATION OF RESULTS**

Considering the results for samples obtained near the Cartersville transverse zone (n=12), muscovite appears to record cooling-crystallization over a range of time between 335-320 Ma (see Table 2). These Middle to Late Mississippian ages have a bimodal cumulative distribution and are suggestive of Serpukhovian and Visean components (Figure 34). Individually, all of these samples yielded simple age distribution regardless of metamorphic textural complexity. These results are consistent with work in the Talladega belt (McClellan et al., 2007), and are interpreted to indicate that Middle to Late Mississippian (Alleghanian) tectonic events dominate metamorphic and structural evolution as far north as the Cartersville transverse zone in the western Blue Ridge.

Figure 34: a) Cumulative-distribution plot of age probabilities for muscovite collected from vicinity of the Cartersville transverse zone. b) Map of sample localities (adapted from Tull and Holm, 2005).

Considering the results for samples obtained farther north (Figure 35), along the Cartersville-Great Smoky fault (n=7), muscovite appears to record a complex cooling-crystallization history. In this region, however, the age distribution tends to form a prominent Visean mode (Figure 35a) similar to the Cartersville samples. Results obtained in this region are consistent with a Mississippian (Visean) age of deformation and metamorphism that is superimposed on relict-mineral assemblages of an earlier metamorphic event.

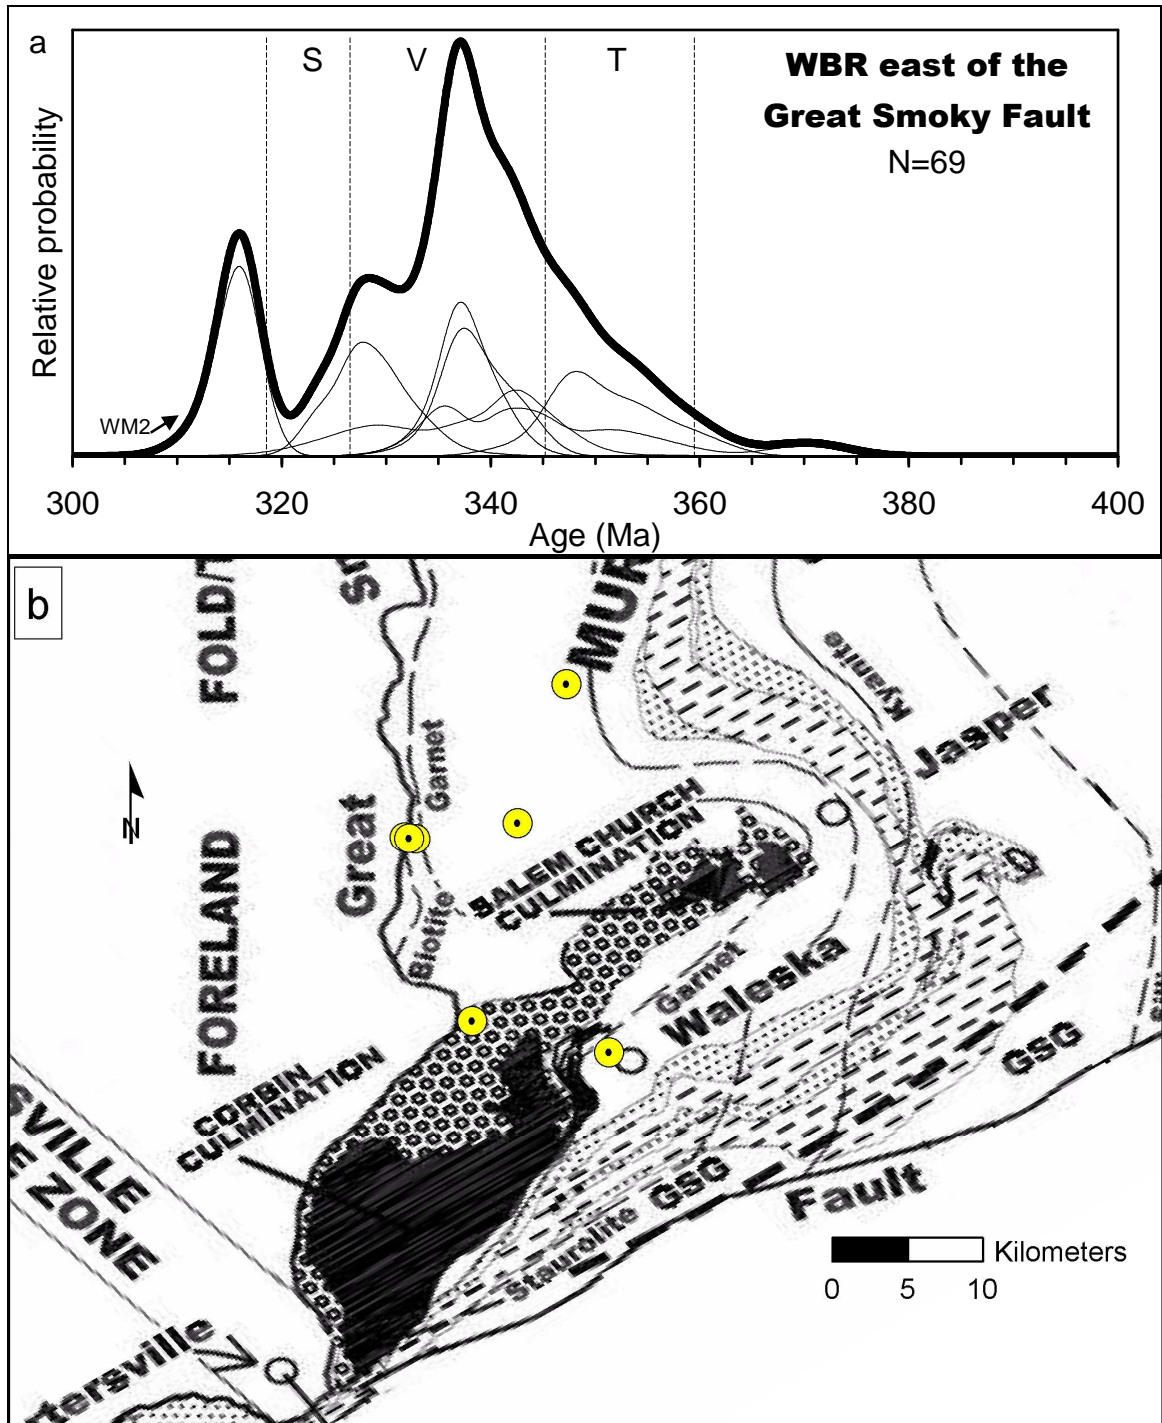

Figure 35: a) Cumulative-distribution plot of age probabilities for muscovite from vicinity of the Cartersville-Great Smoky fault. Sample WM2 (315.5 Ma) yielded the youngest age in this study. b) Map of sample localities (adapted from Tull and Holm, 2005).

Muscovite sampled proximal to the Great Smoky fault, at Carter Lake and Chatsworth, yielded pre-Carboniferous ages with a complex cumulative distribution, showing prominent Middle to Late Devonian modes (Figure 36). Individually, these samples generally yield complex age distributions, have complex metamorphic textures, show evidence of cataclasis, and are considered unreliable due to possible extraneous argon and presence of detrital or relict micas. The Chatsworth sample (WM10) yielded a pre-Carboniferous age with a simple age distribution, showing a prominent Late Devonian peak (Figure 36). A pre-Carboniferous history, possibly relict (Acadian or Taconian), is recorded in western Blue Ridge rocks north of Carter Lake, but that history cannot be discerned from data of this study.

Figure 36: a) Cumulative-distribution plot of age probabilities for muscovite collected farther north (Carter Lake and the Fort Mountain structure) and more directly from fault, yield pre-Carboniferous ages. b) Map of sample localities (adapted from Tull and Holm, 2005).

Considering the results for samples obtained to the northeast, along the Ducktown-Murphy transect (Figure 37), muscovite yielded a complex cooling-crystallization history in Ocoee Supergroup rocks (Ducktown anticlinorium) with prominent Visean and less prominent Tournaisian cumulative-distribution modes. Samples from this transect in rocks of the Mineral Bluff Group (MS-5, MS-6, MS-7, and MS-8; Figures 30, 32, and 33) have a strong tendency to yield normal distributions with prominent Visean modes. A small percentage of the muscovite yielded pre-Carboniferous ages, interpreted to reflect polymetamorphism, relict or detrital grains, the result of accumulating extraneous argon, or combinations of these effects. These results indicate that north of the Cartersville transverse zone, Early-Middle Mississippian (Alleghanian) tectonic events dominate metamorphic and structural evolution in rocks above the Lay Dam unconformity (Mineral Bluff Group). Below the unconformity (Ocoee Supergroup rocks), a record of early-generation muscovite growth is overprinted by Alleghanian tectonothermal effects.

Figure 37: a) Cumulative-distribution plot of age probabilities for muscovite collected from the Ducktown-Murphy structures. b) Map of sample localities (adapted from Tull and Holm, 2005).

## DISCUSSION

Middle Mississippian (Visean) ages recorded in muscovite from phyllites and schists of the western Blue Ridge-Talladega belt (see Figure 38) are interpreted to record metamorphism, ductile deformation, and synchronous rapid cooling. These Visean ages are somewhat older than the traditionally accepted Pennsylvanian range for the age of the Alleghanian event (e.g., Hatcher, 1987). The Alleghanian, therefore, comprises orogenic events as old as Early Mississippian. Furthermore, these ages are substantially younger than the Late Devonian to Early Mississippian 'Neoacadian' event (e.g., Hatcher, 2004, 2006). Considering the low metamorphic grade of rocks dated in this study - and thus short time for any post-metamorphic cooling to significantly affect ages - the Visean ages of this study are not likely to result from a Neoacadian event.

The youngest rocks of the southern Appalachian Valley and Ridge (including the lower Pennsylvanian Pottsville Formation) contain syn-orogenic strata that were overridden and deformed by the final emplacement of the western Blue Ridge-Talladega belt (Figure 39). Dominantly Visean ages recorded in muscovite of the western Blue Ridge-Talladega belt are older than the Pottsville Formation. This means the muscovite in low-grade metamorphic rocks of the western Blue Ridge-Talladega belt crystallized and cooled in a distal location, presumably far to the east of their present location, prior to final emplacement and juxtaposition with the Valley and Ridge province.

Figure 38: Visean (Mississippian) ages recorded in muscovite of this study (mean ages from Table 2 with error bars representing one standard deviation are shown to the right), in comparison with divisions of the Carboniferous Period. The ‘GTS 2004’ of the International Commission on Stratigraphy (Gradstein et al., 2004) is the timescale used in this study. See Gradstein et al. (2004) for additional references to earlier timescale versions in this figure. The comparison of timescales above was created with utilities in the International Commission on Stratigraphy web site: <http://www.stratigraphy.org>.

Figure 39: Map of study area showing the distribution of Mississippian ages yielded from rocks of the western Blue Ridge – Talladega Belt and the general stratigraphy of deformed-clastic units in the foreland (adapted from Tull and Holm, 2005). See Table 2 for specific sample coordinates.

Pre-Carboniferous ages recorded in muscovite from schists proximal to the Great Smoky fault and the transect through the Ducktown and Murphy structures are interpreted to reflect Taconian metamorphism and a protracted thermal history. However, it is possible that the effects of extraneous argon, and ‘inheritance’ of detrital mica, may have strongly influenced these older ages.  $^{40}\text{Ar}/^{39}\text{Ar}$  analyses using incremental-heating methods would clarify the interpretation of these ages because those methods provide a convenient test for the presence of extraneous argon. All ages recorded in muscovite from phyllites near the Cartersville transverse zone of the western Blue Ridge–Talladega belt, and within the Mineral Bluff Group (Murphy synclinorium), tend to define normal distributions and occur within a range from 325–335 Ma. These Visean ages are interpreted to correspond with intense Middle-Late Mississippian deformation and a single, dominant low-grade Alleghanian metamorphic event having affected these units. This finding is consistent with the inference that the Lay Dam Formation (Talladega belt) and Mineral Bluff Group (western Blue Ridge) show evidence of a single low-grade metamorphism (Tull, 1988).

## CONCLUSIONS

Middle Mississippian (Visean) ages of ca. 330 Ma record an “early” Alleghanian event, which affected the Laurentian margin, in muscovite from lower-greenschist phyllites and schists of the western Blue Ridge-Talladega belt. These ages are interpreted to record metamorphism and ductile deformation in those terranes, likely synchronous with rapid cooling. No record of pre-Carboniferous thermal disturbance is present, proximal to the Cartersville transverse zone, in muscovite from Lay Dam Formation and Mineral Bluff Group phyllites. Single-crystal ages older than Carboniferous are also relatively rare, farther north, in Mineral Bluff Group phyllites inside the Murphy synclinorium.

The Visean ages do not record final emplacement of the western Blue Ridge-Talladega belt onto non-metamorphosed rocks of the Valley and Ridge province. As final emplacement of the western Blue Ridge-Talladega belt metamorphic terrane occurred along the dominantly brittle Great Smoky-Cartersville thrust and Talladega thrust. Dynamic metamorphism along the thrusts was sufficiently low in metamorphic grade not to result in substantial growth and recrystallization of muscovite.

The present author interprets the Alleghanian orogeny in the southern Appalachians to comprise multiple Early Mississippian to Permian events. First, during the Mississippian, terrane accretion and continent-continent collision resulted in regional metamorphism and the associated ductile deformation and muscovite growth. Later,

during the Pennsylvanian to Permian, further thrusting of this metamorphosed coastal margin terrane resulting in brittle deformation and final emplacement onto the Valley and Ridge province.

A Taconian metamorphic event and subsequent protracted thermal history is interpreted to be reflected in the complex single-crystal age distributions typical of muscovite found in phyllites and schists of the western Blue Ridge below the Lay Dam unconformity and away from the Cartersville transverse zone. As there are complex distributions of single-crystal ages in these polymetamorphic rocks, techniques that tend to homogenize muscovite (specifically, K/Ar sample processing and *in vacuo*  $^{40}\text{Ar}/^{39}\text{Ar}$  incremental-heating analyses) seem likely to yield average, or hybrid, results that may not accurately record geologic history.

Laser single-crystal measurements of FC-2 (prepared by New Mexico Tech; 20-28 mesh size), and J-values calculated assuming an age of 28.02 Ma (Renne et al., 1998). Data are in moles, corrected for mass discrimination, blank, and interfering nuclear reactions. Errors are quoted as the standard deviation, and a weighted mean J-value is presented for each
