Elizabeth H. Schwartz, Assistant Professor of Biological Sciences

Abstract

The emergence of multidrug-resistant pathogens has increased the demand for discovery of novel antibiotics. Both culture-dependent and culture-independent approaches were used to discover antibiotics against methicillin-resistant clinical isolates of *Staphylococcus aureus* (MRSA). A collection of 548 bacterial and fungal isolates were isolated from soil using low-strength (1/200th) nutrient agar supplemented with soil extract incubated for more than three months. Two isolates, designated as A115 and F4, were found to inhibit the growth of pathogenic MRSA strains. The isolate A115, member of the genus *Streptomyces*, produces pink pigments after extended incubation. The isolate F4, identified as *Nonomuraea*, produces a high molecular weight (>100kDa), heat-stable reddish pigment with anti-MRSA activity. Whole genome sequencing using a combination of shotgun and mate-pair next-generation sequencing resulted in the complete assembled genome for each isolate, with the size of the A115 and F4 genomes at 8.6 Mbp and 10.3 Mbp, respectively. The %G+C contents of strains A115 and F4 were determined to be 71% and 70.4%, respectively. Phylogenetic analysis using six housekeeping genes revealed that strain A115 was most closely related to *Streptomyces afghaniensis* and *Streptomyces olindensis*; however, the low level of average nucleotide identity (ANI) values in comparing the A115 genome were 89.76% and 89.14% for *S. afghaniensis* and *S. olindensis*, respectively. These genomic results, combined with differentiation of strain A115 from other *Streptomyces* species by morphological and physiological characteristics, led to the conclusion that strain A115 is a novel species of the genus *Streptomyces*, for which the name

Streptomyces alburnustigris sp. nov. is proposed. *In silico* analysis using anti-SMASH predicts that A115 and F4 genomes encode many genetic clusters for secondary metabolite biosynthesis, including the synthesis of terpene, aminoglycoside, thiopeptide, bacteriocin, oligosaccharide, phenazine, butyrolactone, siderophore, melanine and potentially other bioactive compounds produced by non-ribosomal peptide synthetase and polyketide synthetase pathways. Both the genomes of *S. alburnustigris* A115 and *Nonomuraea* spp. strain F4 are predicted to encode Type I, II, and III PKS pathways. A large collection of plant growth-promoting rhizobacteria (PGPR) (n=147) isolates were screened for anti-MRSA activity, among which five *Bacillus* strains were identified with anti-MRSA activity. One of these five, *B. amyloliquefaciens* strain AP183, was found to produce a novel macrodiolide compound described herein as bacillusin A with potent anti-MRSA activity of a minimum inhibitory concentration of 0.6 µg/mL. Based on itsnovel biochemistry and strong *in vivo* anti-MRSA activity, strain AP183 was selected for evaluation as a skin probiotic to prevent MRSA infection using a mouse wound model. *In vivo* studies showed that co-administration of secondary metabolites and AP183 spores resulted in a significant reduction in the number of *S. aureus* that colonized mouse skin compared to a negative control. Analysis of 16S rRNA genes PCR amplified from skin samples revealed a significant reduction in the relative abundance of *S. aureus* after AP183 application while the relative abundance of other bacterial taxa increased in the skin microbiome as a result of probiotic administration. Using a culture-independent approach to identify antibacterial compounds, a large-insert soil metagenomic library was constructed that comprised of 19,200 *E. coli* clones with an average insert size of 110 kb. The library clones were screened for anti-MRSA activity using a 96-well microtiter plate. *In situ* lysis of the *E. coli* host enabled detection of both intra- and extracellular compounds, yielding a total of 28 clones that consistently inhibited MRSA growth.

Transformation of naïve *E. coli* with BAC DNA isolated from anti-MRSA clones confirmed the presence of their anti-MRSA activity. Seven of the clones were capable of modifying chloramphenicol added to the *E. coli* culture medium, thereby resulting in modification of an existing antimicrobial scaffold. LC-MS analysis of the organic extract of the clones revealed three new chloramphenicol derivatives. Chemical synthesis of these derivatives showed antimicrobial activities against diverse group of pathogens including MRSA, *Mycobacterium intracellulare* and *M. tuberculosis*. Together with all these results demonstrate that both culture-dependent and –independent approaches can be used to identify previously undescribed bioactive compounds with antimicrobial activity that can be used to control multidrug-resistant pathogens.

Acknowledgments

At this time, I would like to give all honor and thanks to God for the many blessings that he has bestowed upon me, in addition to the endurance and strength given to complete my graduate school journey. I would also like to whole-heartedly thank my loving parents and husband for all of the effort, time and money that they invested in me. Without them, my journey definitely would have been cut short a long time ago. The many times I was indecisive, they were always there to either offer words of wisdom or countless words of encouragement.

I express my sincere and heartfelt gratitude to my major advisor Dr. Mark R. Liles. His timeless and well-tested patience, encouragement and never-ending support have helped me to reach new-found heights as well as expand both my research and general knowledge. Because of Dr. Liles' tremendous efforts, I have learned the true meaning of the word "independent thinking" that will definitely help me to build up my career as a researcher. I would like to gratefully thank my advisory committee member Dr. Peter Panizzi of Auburn University Harrison School of Pharmacy, who consistently guided me in conducting my research using mouse model and in vivo imaging. Very special thanks go to my advisory committee member Dr. Paul A Cobine for his valuable advice and help in completion of this journey. I would also send appreciation to Dr. Elizabeth H. Schwartz and Dr. Joseph W. Kloepper for their much needed assistance in addition to their participation as members of my dissertation committee.

I would also like to thank members of Dr. Cobine's lab, Dr. Panizzi's lab and Dr. Kloepper's lab, who helped many ways to conduct my experiments and make my time in the Auburn more fun and interesting.

Special thanks go to my colleagues in Dr. Liles lab, Nancy Capps, Ran Chao, Malachi Williams, Dr. Abel Carrias, Dr. Kavida Kakirde, Dr. Molli Newman, Dr. Dawei Sun, Charles Thurlow, Jinglie Zhou, Alinne Pereira, Cody Rasmussen-Ivey, Alysa Moore and Erin Schmale for their constant support and encouragement.

I am very thankful to my brother-in-law Mohammad Kamrul Hassan for his inspiration and help. I am also very thankful to my Bangladeshi friends here at Auburn who made my life enjoyable in abroad.

I would like to express my sincere love and utmost gratitude to my husband Mohammad Jahangir Hossain for all the support he has given me to continue my graduate school journey. Without his support and encouragement I might not be able to cross this long path. I would like to express my unconditional love to my daughter Sarina J. Naureen. Her smiley face always cheers me up for conducting my experiments over and over.

Literature review

1.1 **Overview of multi-drug resistant pathogens**

Bacterial pathogens that are resistant to multiple drugs represent a growing public health threat as there are fewer, or even sometimes no, effective antimicrobial agents available for treating infections caused by these bacteria. Infectious diseases caused by multi-drug resistant (MDR) bacteria are a significant global public health concern. In the United States, the mortality rate due to infectious diseases was significantly low only 59 deaths per 100,000 (Armstrong et al. 1999) in 1996 but is a significant healthcare burden with 4.5 million hospital days costing $96 billion in 2008. Smolinski et al. (Smolinski et al. 2003) and Morens et al. (Morens et al. 2010) reported the increased risk of emerging infections in the USA and highlighted the nation's crumbling public health infrastructure, and called for substantial improvements in the USA's capacity to address these mounting challenges.

Six species of bacteria are responsible for two thirds of all health care-associated infections (HAI) in the USA (Bandeira et al. 2014) including *Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella* species, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*,

and *Enterobacter* sp. (also known as the ESKAPE pathogens) (Bandeira et al. 2014). Strains from these pathogens were found to be drug resistance for all known drug classes and poses a significant challenge for anti-infective therapy (Pendleton et al. 2013; Boucher et al. 2009). In addition, most of the ESKAPE bacteria have the ability to form biofilms which can worsen the situation by making these bacteria to persist in hospital units and to increase antibiotic resistance (Bales et al. 2013).

Currently, the most notorious bacterial pathogen is the Gram-positive organism *Staphylococcus aureus*. *S. aureus* is a facultative anaerobe and present as a nasal commensal in 30% of the population (Fair et al. 2014). Though traditionally opportunistic, in recent years, many *S. aureus* strains have evolved as aggressively pathogenic,causing the major nosocomial infections (Davies et al. 2010). National Nosocomial Infection Surveillance (NNIS) System data indicate a steady increase in the incidence of nosocomial infections caused by methicillin-resistant *S. aureus* (MRSA) among intensive care units (ICUs) patients over time and now accounts for over 60% of *S. aureus* isolates in US hospital ICUs (NNIS report 2004). *S. aureus* was also identified as one of the most frequent nosocomial pathogens in European ICUs (Vincent et al. 1995). MRSA is associated with significant morbidity and mortality and is the causative agent for both the hospital care and community associated infections (Klein, Smith et al. 2007). In the US, hospital acquired infections are the fourth cause of death, taking 100,000 lives and adding $30 billion to hospital costs per year (McCaughey 2006; Hassan, Tuckman et al. 2010). *S. aureus* infections alone cost $14.5 billion in 2003 (Noskin, Rubin et al. 2007) and took approximately 19,000 lives in 2005 (Klevens R and et al. 2007). The estimated number of deaths due to MRSA infections exceeds that due to HIV/AIDS (Klevens R and et al. 2007).

1.2 **General features of *S. aureus***

S. aureus is a member of the phylum *Firmicutes,* belongs to the family Staphylococcaceae and appears as cocci in clusters under microscopy. *S. aureus* can be distinguished from other staphylococcal species on the basis of the golden pigmentation of colonies and biochemical characteristics (i.e. positive for coagulase, mannitol-fermentation, and deoxyribonuclease) (Wilkinson, 1997). *S. aureus* genome consists of a circular chromosome with approximately 2.8 Mbp nucleotides (Davis et al. 2013). Its genome contains prophages, transposons and plasmids which play an important role in virulence and antibiotic resistance mechanisms.

1.3 **Disease caused by *S. aureus***

S. aureus is the most commonly isolated bacterial pathogen of humans, causing infections which can be divided into three categories: a) superficial infections such as mild skin and soft tissue infections (Vincent et al. 2008), wound lesions, b) toxinoses such as toxic shock syndrome and food poisoning, and c) life-threatening systemic infections, including pneumonia (Rubinstein et al. 2008), endocarditis (Panizzi et al. 2011), bacteremia, sepsis, metastatic infections in distal part of the body, and osteomyelitis (Lowy, 1998). *S. aureus* can also cause diseases in several other animals including reptiles, birds and non-human mammals (van Leeuwe et al. 2005), particularly, dogs, cows, horses, goats, sheep and camel (Sung et al. 2008). *S. aureus* is the most common cause of mastitis in cattle and comparative genomic of *S. aureus* genomes revealed that the animal-associated *S. aureus* strains clustered into ten lineages which are unique to animals (Sung et al. 2008).

1.4 **Virulence factors produced by *S. aureus***

Pathogenic *S. aureus* produces a plethora of virulence factors for attachment of bacterial cells to the host cell, colonization in the host, evading host immune defense, persistence and penetration in host tissue. Virulence factors produced by *S. aureus* include surface-associated adhesins, extracellular enzymes and exo-toxins (Lowy, 1998). It is difficult to sort out the role of individual virulence factor in the pathogenic process of staphylococcal infection because of the functional redundancy of *S. aureus* virulence factors and multifactorial nature of *S. aureus* infections (Novick, 2000).

1.4.1 **Cell surface-associated virulence factors**

1.4.1.1. **Adhesins**

Proteinaceous Staphylococcal Adhesins

Initial infection begins when cells of *S. aureus* adhere to the components of extracellular matrix or host tissue or to abiotic surface such as medical devises and the adherence is mediated by proteinaceous surface adhesins known as microbial surface components recognizing adhesive matrix molecules family (MSCRAMMs) and non-proteinaceous adhesins (Lowy, 1998). Among all the members of MSCRAMMs family, collagen-binding protein (Can), fibrinogen-binding clumping factor A and B (ClfA and ClfB), and fibronectin binding protein A and B (FnBPA and FnBPB) are the most important adhesins of *S. aureus* (Jonsson et al. 1991; Patti et al. 1992; Menzies, 2003). MSCRAMMs family proteins are one of the major classes of *S. aureus* adhesins that covalently linked to the cell wall peptidoglycan via the threonine residue in the signal motif at their C-terminus (Foster et al. 1998; Speziale et al. 2009; Marraffini et al. 2006). These adhesin proteins specifically mediate attachment of bacteria to the plasma or extracellular matrix (ECM) components including fibronectin (Fn), fibrinogen (Fg), vitronectin (Vn),

thrombospondin, bone-sialoprotein, elastin, collagen, and von Willebrand factor which facilities direct adherence to host tissue (Flock et al. 1987; Cheung et al. 2002).

In addition to bacterial cell wall anchored adhesins, several non-covalently linked surface associated proteins also play important role during attachment of *S. aureus* in host tissue, such as autolysin (Hirschhausen et al. 2010), secretable expanded repertoire adhesive molecule SERAMs (Chavakis et al. 2005) and membrane-spanning proteins (Clarke et al. 2006). These non-covalently bound proteins are associated with the surface by ionic, hydrophobic or so far unknown interactions. In case of autolysin, AtlE which was first identified as *S. epidermidis* surface associated component, later found homology to *S. aureus* autolysin AtlE has an important role in attachment to polystyrene, biofilm formation and adherence to Vn (Heilmann et al. 1997; Biswas et al. 2006). Hirschhausen et al. demonstrated that Atl/AtlE can also binds to Fg, Fn, Vn and human endothelial cells and functioning staphylococcal internalization by endothelial cells (Hirschhausen et al. 2010). The Atl- or AtlE-mediated internalization mechanism is the sole mechanism involved in the internalization of coagulase-negative staphylococci. However, in coagulase-positive, *S. aureus* it might be a backup internalization mechanism (Hirschhausen et al. 2010).

Another example of non-covalently linked surface-associated proteins are SERAMs that include fibrinogen binding protein A (FbpA), coagulase (Coa), von Willebrand factor binding protein, extracellular fibrinogen binding protein (Efb), extracellular matrix binding protein (Emp) and extracellular adhesive protein (Eap) both have broad binding spectrum to host ligands and play an important role in endovascular infection. Among all the SERAMs, Eap and Emp are the two main molecules that bind to the components of the extracelluar matrix and mediate attachment and colonization of *S. aureus* cells on host tissue. The role of these proteins was

confirmed in deletion mutants with loss of *eap* and *emp* genes showed reduced ability to colonize and invade host tissue (Chavakis et al. 2005).

Other secretable proteins such as *S. aureus* coagulase (Coa), fibrinogen binding protein A (FbpA) and von Willebrand factor binding protein have homologous domain to Coa and play significant role in bacterial pathogenesis of endovascular infections. Panizzi et al. demonstrated the role of staphylocoagulase as a virulence factor in endocarditis and present evidence for its regulation by bacterial quorum sensing mechanism (Panizzi et al. 2011). The Efb protein interacts with the α chain of fibrinogen thus inhibiting aggregation of platelets which impaired fibrin formation, resulting disruption of wound healing in experimental wound model (Palma et al. 2001; Shannon et al. 2004). Literature showed that Efb not only bind to fibrinogen but also involved in counter-acting host defense by binding to complement component C3b, thus inhibiting complement mediated phagocytosis of invading bacterial cells (Lee et al. 2004; Lee et al. 2004; Lambris et al. 2008).

Additional non-covalently anchored cell surface proteins are extracellular matrix-binding protein homologue (Ebh) for *S. aureus* and extracellular matrix-binding protein homologue (Embp) for *S. epidermidis* (Clarke et al. 2006; Williams et al. 2002). The proteins Ebh and Embp bind with Fn; however, binding sites of Ebh and Embp are not similar and they were encoded from the largest genetic regions of *S. aureus* and *S. epidermidis* genomes, respectively. Further non-covalently anchored surface protein is elastin-binding protein of *S. aureus* (EbpS), is an integral membrane that binds with a major component of the extracellular matrix, elastin (Downer et al. 2002).

Non-proteinaceous Staphylococcal Adhesins

Polysaccharide intercellular adhesin (PIA) was first identified in *S. epidermidis*, and later it was also found in *S. aureus* (Mack et al. 1996; Cramton et al. 1999) with a clear role in biofilm formation. PIA is encoded by the *icaADBC* operon and is present in most of the *S. aureus* strains (Rohde et al. 2001). The role of PIA as a virulence factor has been confirmed in *S. epidermidis* mediated foreign-body infection model (Gotz, 2002; Heilmann et al. 2010); however, its role in *S. aureus* virulence was not clearly demonstrated, and conflicting results were later reported (Kristina et al. 2004).

Wall teichoic acids (WTA) and lipoteichoic acids (LPA) are non-proteinaceous highly charged cell wall polymers that have role in *S. aureus* colonization, infection, and immune evasion (Brown et al, 2013; Xia et al, 2010). The WTA is covalently linked to the peptidoglycan, whereas the lipoteichoic acid is attached to the cytoplasmic membrane via glycolipid. Biosynthesis of lipoteichoic acid is catalyzed by the enzyme glycolipid synthase, YpfP, and mutation in *ypfP* markedly decreased the production of lipoteichoic acid resulting in reduced ability to form biofilm on a polystyrene surface (Fedtke at al. 2007).

1.4.1.2 **Capsular polysaccharides**

Karakawa et al (Karakawa et al. 1988) found that most of the *S. aureus* strains were encapsulated, and a quarter of recovered human isolates belonged to the serotype CP5 and CP8 (Arbeit et al. 1984). Encapsulated bacteria are highly resistant to phagocytosis as compared to their counterpart, resulting in bacterial persistence in the bloodstream of the infected host (Karakawa et al. 1988; O'Riordan et al. 2004). Further roles of capsular adherence to endothelial surfaces resulting in involvement in colonization and persistence on mucosal surfaces were confirmed by several *in vitro* and *in vivo* studies, respectively (O'Riordan et al. 2004; Nanra et al. 2013).

1.4.2 **Secreted virulence factors**

The secreted virulence factors of *S. aureus* are usually produced at the stationary phase of growth and are involved in detoxifying various innate immune mechanisms (Schlievert et al. 2010). They also make nutrients available to the bacteria, thus promoting growth inside the host. A number of secreted factors are produced by *S. aureus* including various exoenzymes, exotoxins, superantigens, staphylococcal enterotoxins (SE) like proteins, toxic shock syndrome toxin-1(TSST-1) and exfoliative toxins A and B (Schlievert et al. 2010).

1.4.2.1 **Exoenzymes**

Various exoenzymes are produced by *S. aureus* such as proteases, lipase, nucleases, hyaluronidase and aureolysin (Costa et al. 2013). Exoenzymes of *S. aureus* are mainly involved in destruction of connective tissue, making nutrients available for the bacteria, facilitating spread of infection by detaching bacterial cells from initial colonization site, inhibiting the activity of clotting and kinin systems, promoting bacterial growth in host fatty acids and directly interacting with host immune cells via inactivation of PMN's mediated host defense (McAleese et al. 2001; Shaw et al. 2004; Kantyka et al. 2011).

1.4.2.2 **Superantigens**

Staphylococcal superantigens are a family of potent immunostimulatory enterotoxin that play major role in invasive infections including toxic shock syndrome (TSS), food poisoning, atopic dermatitis (AD), Kawasaki disease (KD), and chronic rhinosinusitis (CRS) (White et al. 1989; Xu et al. 2012). The superantigens of *S. aureus* include staphylococcal enterotoxins (SEs; A, B, C, D, E, G, H, I, and R), SE-like proteins (SEls; J, K, L, M, N, N, O, P, Q, S, U, V, and X), TSST-1 and exfoliative toxins A and B (Schlievert et al. 2010; Xu et al. 2012). Most of the clinical *S. aureus* strains possess at least one superantigen encoding gene in their genome which

functions to stimulate T cells (Barsumian et al. 1978; Schlievert et al. 1981) and macrophages (Marrack et al. 1990) to produce massive amounts of cytokines such as interleukin-1β (IL-1β), IL-2, tumor necrosis factor-α (TNF-α), TNF-β and interferon-γ (IFN-γ) (Schlievert et al. 2010). Superantigens stimulate T cells by bypassing the usual pathway of antigen-mediated immune response, usually antigens are processed by antigen presenting cells and processed antigen fragments then expressed on the surface of the major histocompatibility complex type II (MHCII). The resulting antigen-MHCII complex then interacts with receptor of T cell thus activating specific T cell mediated immune response. However, superantigens are not presented by antigen-presenting cells. Instead, they bind directly to the MHCII complex where they can interact with T cell receptors. Since superantigens are not presented by antigen- presenting cells, they activate T cells non-specifically. This non-specific activation of large number of T cells results in massive production of cytokins. Several studies have shown that these cytokines can mediate clinical symptoms such as fever, rash, hypotension, tissue injury, and shock (Stevens et al. 1989; Hackett et al. 1992; Leung et al. 1995; Bronze et al. 1996; Johnson et al. 1996).

1.4.2.3 **Exotoxins**

S. aureus produces a large repertoire of exotoxins that possess highly inflammatory cytolytic activity. Cytolytic toxins cause cell death by forming pores in the membrane of the target cell (Bien et al. 2011). Single *S. aureus* strain can secret a number of cytolytic toxins including hemolysins (α, β, γ), leukocidin and Panton-Valentine leukocidin (PVL) (DuMont et al. 2013). Hemolysins, including α and β have the ability to damage the membrane of host immune cells by osmotic lysis through the formation of pores in the membrane of platelets and monocytes. Leukocidins such as LukED and LukAB are cytotoxic for innate immune cells, including lymphocytes, macrophages, and dendritic cells and play an important role in *S. aureus*

infections (Alonzo et al, 2013). LukAB leukocidin was identified in 2011 (Dumont et al. 2011) and found that it specifically targets phagocytic cells such as polymorphonuclear (PMN) cells or neutrophils. In 2013, DuMont et al. identify cellular receptors for LukAB-mediated cytotoxicity and demonstrated their role in species specificity (DuMont et al. 2013). PVL, hetero-chain containing heptamer pore-forming cytolytic toxin is highly cytotoxic to human PMNs (Schlievert et al. 2010). However, PVL showed minimum cytotoxicity to mouse PMNs in a pulmonary disease model. Furthermore, both PVL^+ and PVL^- *S. aureus* strains were lethal for mice when administered intra-bronchially (Schlievert et al. 2010).

Biofilm formation is another virulence strategy which allows *S. aureus* to persist on host tissue or to the surface of a medical device and resist host defenses or antibiotics (Foster, 2005). Generation of small colony variants is another virulence mechanism which helped *S. aureus* survival in a metabolically inactive state under harsh conditions. Small colony variants have an association with chronic, recurrent and persistent infections such as chronic osteomyelitis and persistent skin and soft tissue infection (von Eiff et al. 2006).

1.5 **Epidemiology of *S. aureus* disease**

Humans are a natural reservoir for *S. aureus*, which is a commensal bacterium known to asymptomatically colonize the human skin, nares, and gastrointestinal tract (Lowy 1998). Individuals colonized with *S. aureus* are at increased risk to develop infections. Risk factors associated with *S. aureus* colonization include intravenous drug use, use of intravascular devices, surgery, immunocompromised or immunosuppressed patient, and patient with type 1 diabetes (Lowy, 1998; Naber, 2009). Transmission of infection occurs mainly by direct contact to a colonized carrier (Chambers, 2001). The rates of infections caused by *S. aureus* have been increased and the treatment options for these diseases are becoming limited because of the

increased resistance of *S. aureus* strains to antibiotics (Corey, 2009). Thus the ability of these bacteria to spread in both community and hospital settings has increased substantially. Earlier investigations on methicillin-resistant strains of *S. aureus* (MRSA) revealed that these strains are largely confined to hospitals and long-term care facilities; however, their prevalence in the community is now well recognized (Saravolatz et al. 1982; David et al. 2010).

1.6 **Pathogenesis of HA-MRSA**

In 1959, methicillin was first introduced and thought to be an antibiotic of choice for almost all of the penicillin resistant *S. aureus* strains. However, in 1961, soon after the introduction of methicillin, the first methicillin-resistant strains were identified in England (Jevons, 1961). Since then, MRSA has become a major nosocomial pathogen that causing severe morbidity and mortality worldwide (Haddadin et al. 2002). Methicillin resistant gene *mecA* is a part of mobile genetic element called the staphylococcal cassette chromosome (SCC) which encodes a penicillin-binding protein 2A (PBP2A). PBP2A binds to the β-lactam antibiotics with lower affinity than the regular PBP of *S. aureus* (Chambers 1997). Hospital-acquired MRSA (HA-MRSA) strains possess large SCCmec types I to III which encode one or multiple antibiotic resistance genes and allow the bacterium to survive under the pressure of antibiotics (Liu, 2009). It was found that HA-MRSA strains rarely causes disease in healthy individuals; however, they can cause invasive infections including pneumonia, bacteremia in people who are exposed to the health care setting; older people and have one or more predisposing conditions (Chambers, 2001). Therefore, it has been suggested that HA-MRSA strains might be less robust than other strains of *S. aureus* in terms of its pathogenesis and virulent determinants. HA-MRSA strains are more susceptible to neutrophils mediated killing and are less virulent when administered to mice systemically (Voyich et al. 2005). Furthermore, HA-MRSA strains expressed low levels of

phenol-soluble modulin (PSM) peptides which raise the possibility that PSMs might have role in reduced virulence of HA-MRSA. In addition, many of the HA-MRSA isolates exhibit a *agr*$^{-}$ or a mixed *agr*$^{+}$ and *agr*$^{-}$ genotype (Shopsin et al. 2008), and the presence of this genotype could explain the relative nonpathogenic nature of HA-MRSA toward immunocompetent hosts and beneficial for HA-MRSA survival in the healthcare setting where bacterial competition is limited by the positive pressure of antibiotics. Vuong et al. (Vuong et al. 2000) also found that *agr*$^{-}$ genotype facilitates biofilm formation and proliferation of HA-MRSA isolates on plastic tubing. Virulence of HA-MRSA isolate is largely depending upon to its ability to form biofilm on indwelling medical devices (Ferreira et al, 2013).

1.7 **Pathogenesis of CA-MRSA**

Until 1990s, MRSA infections were mainly confined to immunocompromised individuals or individuals with healthcare exposure and it rarely caused infections among community members without exposure to the health care setting. In the late 1990's four healthy children died in the USA from MRSA sepsis and pneumonia (CDC report 1999). That was the first report of MRSA infections which was occurring among healthy people in the community without health care exposure. Since then a number of reports had been published which had described the emergence of new community-acquired MRSA (CA-MRSA) strains (Groom et al. 2001; Baggett et al. 2003; Liu et al. 2009) that were markedly different from HA-MRSA. CA-MRSA strains are genetically different from HA-MRSA strains, shared a small sized type IV SCC*mec* cassette, and encoded the genes for the Panton-Valentine Leukocidin (PVL) (Vandenesch et al. 2003).

CA-MRSA strains largely caused skin and soft tissue infections; however, several reports have found their connection with more severe infections such as necrotizing pneumonia, necrotizing fasciitis, and myositis (Bradley, 2003; Miller et al. 2005; Pannaraj et al 2006). One

CA-MRSA clone, named USA300 spreads rapidly and is inked to more severe bone, skin and soft tissue infection (Miller et al. 2008). Furthermore, the rate of skin colonization is significantly higher in CA-MRSA infected individuals than the HA-MRSA and MSSA infected individuals. Together, these observations suggest that clone USA300 is more virulent because of its rapid transmission capacity, ability to colonize efficiently and unique mode of pathogenicity. Though the clone USA300 has been proven to be the most virulent isolate but it is not known whether other clones of CA-MRSA are equally virulent. The major virulence determinants of the CA-MRSA epidemic strain include PVL, *arc* gene in arginine deiminase system, *opp-3* gene in ABC-transporter and PSM peptides (Boyle-Vavra et al. 2007; Diep et al. 2006; Wang et al. 2007). However, the role of each virulent factor in the pathogenicity of the specific strain is not known.

1.8 Host defense mechanisms to MRSA infections

S. aureus can survive both outside and inside of host cells. Host cells that provide support for intracellular growth of *S. aureus* are epithelial cells, endothelial cells, and even macrophages (Kubica et al. 2008). Neutrophils play critical roles by providing first line of defense against invading *S. aureus*. The roles of neutrophils in providing a rapid, non-specific, and potent response to infections are manifested by increased incidence of recurrent invasive *MRSA* infections of neutrophil dysfunction immune system (Dinauer et al. 2000). PMN are part of the innate immune system, rapidly migrate to sites of infection where they bind and engulf invading *S. aureus (*Rigby et al. 2012*)* for phagocytosis which triggers potent oxidative and non-oxidative antimicrobial killing mechanisms, including generation of reactive oxygen species (ROS) and antimicrobial proteins that serve to limit pathogen survival and dissemination (Babior et al. 1973; Bainton et al. 1968). PMN activation is intimately linked with the production of

superoxide and other secondarily derived ROS, such as hypochlorous acid, hydroxyl radical, chloramines, and singlet oxygen that have proven microbicidal activity (Rigby et al. 2012). Furthermore, neutrophil mediated phagocytosis triggers synthesis of a number of immunomodulatory factors (Kobayashi et al. 2003; Borjesson et al. 2005; Scapini et al. 2000) which recruit additional neutrophils, modulate subsequent neutrophil responses, and coordinate early responses of other cells types such as monocytes, macrophages, dendritic cells and lymphocytes thereby providing an important link between innate and acquired immune responses (Rigby et al. 2012).

The progression of disease followed by infection triggers acquired immune responses which are responsible for clearance of invading pathogens and providing long term immunologic memories. B-cell and T-cell mediated responses, which are part of adaptive immune system, are involved in antibody production and cell-mediated defense against specific antigen of *S. aureus*, respectively (Girardi, 2007). In B-cell mediated immune responses against *S. aureus*/MRSA infections, many antibodies are generated against toxins, cell-wall proteins, capsular polysaccharides and other virulence factors (Holtfreter et al. 2010). These newly generated antibodies then opsonize the bacteria to facilitate complement-mediated ingestion of *S. aureus* (Holtfreter et al. 2010). In addition to opsonization and phagocytic responses of antibodies, other host defense system includes inhibition of cytolytic activity of α-toxin and PVL toxins and inhibition of *S. aureus* nutrient uptake (Kennedy et al. 2010; Bubeck et al. 2008; Brown et al. 2009). Furthermore, T helper cell subsets (CD4+ T cells) play an important role in the pathogenesis of *S. aureus* skin infections by producing a number of cytokins including IFN-γ, IL-4, IL-13, IL-17, IL-21 and IL-22 (O'Shea et al. 2010). These cytokins promote neutrophil recruitment, cell-mediated and antibody mediated immune responses (O'Shea et al. 2010;

Krishna et al. 2012). It is important to understand the mechanisms of protective immune responses against *S. aureus* infections for the future development of immunomodulatory therapies and vaccination strategies to prevent infections caused by *S. aureus*.

1.9 **Current treatment options for MRSA infections**

The increasing antimicrobial resistance and a variety of diseases, including invasive and noninvasive infections, caused by MRSA are limiting factors for treating MRSA infection. The treatment of MRSA infections is also limited by the ability of MRSA strains to produce biofilm in tissues and medical devices (Mazaitis et al. 2011). A number of antibiotics are currently being used for the treatment of MRSA infections. For the treatment of minor skin infections including small furuncles and abscesses, surgical incision and drainage of pus combine with oral antibiotic therapy is the first choice of treating MRSA infection. Oral antibiotics for the treatment of CA-MRSA infections include linezolid, rifampin with/without fusidic acid, trimethoprim-sulfamethoxazole, doxycycline, minocycline, clindamycin (Moellering, 2008). Linezolid is the only oral agent that is currently used for the treatment of CA-MRSA infections in outpatients (Moellering, 2008). In case of serious skin and skin-structure infections and pneumonia due to CA-MRSA, linezolid might be particularly useful because of its ability to impair toxin production (Moellering, et al. 2008; Ramirez et al. 2012). Though the application of linezolid for the treatment of MRSA provided apparent advantages (Micek 2007), certain safety concerns including serotonin toxicity and thrombocytopenia limit the applicability of this antibiotic for treating MRSA infections (Kishimoto 1995; Lawrence, Adra et al. 2006). Additional parenteral antimicrobials such as vancomycin, teicoplanin, daptomycin, linezolid, and tigecycline can be used for treating severe infections due to CA-MRSA. Most recently the U.S. Food and Drug Administration (FDA) approved dalbavancin and tedizolid phosphate, a lipoglycopeptide and

protein synthesis inhibitor antibiotics respectively, for treating adult patients with acute bacterial skin and skin structure infections (ABSSSI) (Walker, 2014). For the treatment of nosocomial pneumonia, vancomycin, linezolid, and teicoplanin antibiotics are currently being used (Kalil et al. 2013; Rivera et al. 2011). Daptomycin is not recommended for use in pneumonia due to MRSA because of its inactivation by pulmonary surfactant (Liu et al. 2011; Ramirez et al. 2012). However, daptomycin is recommended for patient with bacteremia and endocarditis (Liu et al. 2011). Vancomycin was introduced into clinical practice in 1958, and was first isolated from the soil Actinobacterium *Amycolatopsis orientalis*. It is a member of the glycopeptide antibiotic family that inhibits the late stages of peptidoglycan assembly by forming complexes with the *D*-alanyl-*D*-alanine (*D*-Ala-*D*-Ala) in C termini of the peptidoglycan precursors on the external side of the cell membrane (Neu et al. 2002). Cell wall assembly is hampered by the formation of these complexes which prevents the cross-linking reaction catalyzed by transglycosylases, *D,D*-transpeptidases, and *D,D*-carboxypeptidases (Beltrametti et al. 2010). Though vancomycin is the first choice of treatment for most of the MRSA infections, its application is limited by the emergence of strains with reduced antimicrobial susceptibility (Davies et al. 2010) and the occurrence of vancomycin treatment failure and mortality in patient with methicillin-sensitive *S. aureus* (MSSA) bacteremia (Graves et al. 2008; Marco et al. 2008). The MIC creep, the incremental vancomycin MIC, is a frequently observed phenomenon in MRSA infected patients with vancomycin treatment (White et al. 2007). Until now eleven vancomycin-resistant MRSA strains have been identified, nine in the USA(7 from Michigan, 1 from Pennsylvania, and 1 from New York) (Périchon et al. 2009). Wide spread use of vancomycin for the treatment of MRSA infection has led to the emergence of two types of glycopeptide-resistant *S. aureus* strains that include vancomycin-intermediate-resistant *S. aureus* (VISA) and vancomycin-resistant *S. aureus*

(VRSA). In addition to antibiotic resistance to vancomycin, side effects caused by vancomycin treatment also impede treatment of MRSA infections. Patients treated with vancomycin may experience nephrotoxicity (Lodise, Patel et al. 2009), “red man” syndrome (Sivagnanam and Deleu 2003) and anaphylaxis (Polk 1991; Neughebauer, Negron et al. 2002). Although MRSA causing significant health care-associated and community-associated infections, the current therapeutic alternatives for MRSA infections are limited to few antibiotics.

1.10 **Resistance mechanisms to antimicrobial agents**

S. aureus is the most versatile bacterial pathogen that has a unique ability to evolve quickly in response to new antibiotic (Lowy, 2003; Reygaert, 2013). It has developed resistance towards a number of antibiotics including penicillin, methicillin, cephalosporins, amikacin, clindamycin, fluoroquinolones, gentamycin, tobramycin, trimethoprim/sulfamethoxazole, vancomycin, linezolid and daptomycin. *S. aureus* confers antibiotic resistance by four general mechanisms including i) enzymatic inactivation of the antibiotic ii) alteration of the target side which led to decrease affinity for the antibiotic iii) trapping of the antibiotic and iv) efflux pumps. Bacteria develop these resistance mechanisms by intrinsic (presence of SCC *mec* gene or *vanA* operon in their chromosome), acquired (through horizontal gene transfer via plasmid, bacteriophage) or through spontaneous mutations and positive selection (Reygaert, 2013).

The mortality rate of patients with *S. aureus* bacteremia before the introduction of antibiotics was more than 80%. However, the mortality rate decreased dramatically after the introduction of penicillin in the early 1940s. In 1944, Kirby (Kirby 1944) was first identified seven *S. aureus* strains that were resistant to penicillin. First penicillin-resistant staphylococci were recognized in hospitals and subsequently in the community (Rammelkamp et al. 1942). Today greater than 95% of all *S. aureus* isolates are resistant to penicillin and the resistance is

primarily mediated by the enzyme *β*-lactamase which is encoded by the gene *blaZ*. The enzyme β-lactamase hydrolyzes the *β*-lactam ring presents in this antibiotic for enzymatic inactivation (Bondi et al. 1945). Resistance to *β*-lactam antibiotics can also be confirmed by the production of an extra penicillin-binding protein, PBP 2a, a transpeptidase encoded by the gene *mecA (Zhang et al. 2001).* The *mecA* gene, which is part of a mobile genetic element found in all MRSA strains, confer resistance not only to methicillin, but also to all other *β*-lactam antibiotics (Lowy, 2003).

With the increasing antimicrobial resistance in *S. aureus*, vancomycin has become the drug of choice for treating infections caused by *S. aureus*. However, indiscriminate use of vancomycin created two types of resistant strains dubbed as vancomycin intermediate *S. aureus* (VISA) and vancomycin resistant *S. aureus* (VRSA). Both strains showed complete resistance to vancomycin but the development of resistance mechanisms were different (Lowy, 2003). The VRSA strains acquire resistance by conjugal transfer of the *vanA* operon from an *Enterococcus faecalis (*Périchon et al. 2004*),* whereas chromosomal resistance was found in VISA strains (Saito et al. 2014). The glycopeptide-intermediate-resistant is associated with a thickened and poorly cross-linked cell wall, resulting in an accumulation of *D*-alanyl-*D*-alanine (*D*-Ala-*D*-Ala) targets in the periphery that sequester glycopeptides(Périchon et al. 2009). Sieradzki et al. (Sieradzki et al. 1999) showed that large amounts of vancomycin become sequestered in the abnormal peptidoglycan that are unable enter into the cell and confer its antimicrobial activity.

Daptomycin is a lipopeptides antibiotic first introduced into market in 2003 for skin and invasive infections (Bayer et al. 2013). Since 2005 an alarming number of reports have been published indicating the *in vivo* development of daptomycin resistance (Vikram et al. 2005; Julian et al. 2007; Murthy et al. 2008; Chambers et al. 2009; Bayer et al. 2013). Daptomycin

resistant strains of *S. aureus* showed altered structure of both cell wall and cell membrane which resulted in cell membrane depolarization, reduced surface binding and permeability of daptomycin. Furthermore, cell wall modifications by increased expression of the *dlt* operon which is involved in D-alanylation of teichoic acids and by thickening of cell wall are found to play important role in daptomycin resistance phenomenon (Ho et al. 2008; Straus et al. 2006; Scott et al. 2007; Bayer et al. 2013).

Linezolid is a synthetic protein synthesis inhibitor, used for the treatment of infections caused by MRSA and VRSA (Tsiodras et al. 2001). Bacteria acquire resistance by spontaneous point mutations at the drug target site or by acquisition of a natural resistance gene, *cfr (*Morales et al. 2010*).* The *cfr* gene is present in plasmids and may be horizontally transferred to S. aureus strains since it was first identified in a bovine *S. sciuri* isolate (Schwarz et al. 2000; Morales et al. 2010).

1.11 **Discovery of new antibiotics for MRSA infections**

Since MRSA infections are continuously challenging the medical and scientific community due to limited treatment options and the emergence of new antibiotic-resistant strains, it is essential to find new antibiotics that will be able to cure MRSA infections. According to the Infectious Diseases Society of America (IDSA), at least ten new antibiotics are needed by 2020 to combat multi drug resistant (MDR) bacterial pathogens (IDSA 2010). To discover new antibiotics with novel mechanisms of action we need to expand our knowledge in conventional culturing approach, novel culture methods, heterologous DNA-based methods, metagenomics, combinatorial biosynthesis and fragment-based drug design.

1.11.1 Discovery of novel antibiotics using a culture-based approach

Several new methods for developing antibiotic have been introduced recently, including genome mining, novel culturing methods, and metagenomics. Decoding the genomes of antibiotic producing microbes has revealed a surprisingly large number of biosynthetic pathways (Bentley et al. 2002; Wilkinson et al. 2007; Nikolouli et al. 2012). *Streptomyces coelicolor* is known to produce only three antimicrobial compounds, even though its genome encodes 20 secondary metabolites (Bentley et al. 2002). Nearly every antibiotic-producing microbial genome examined bioinformatically contains multiple pathways for secondary metabolites (Nikolouli et al. 2012). Unfortunately these cryptic pathways are mostly silent and efforts to turn them on have succeeded, but not as a large scale platform (Lewis, 2013). Culture-based approaches have recently gotten new momentum due to technology advancements such as whole genome sequencing, high-throughput screening and cultivating as-yet unculturable microorganisms using new cultivation approaches (Baltz 2008). culture-based strategies are still the most successful method for discovering clinically useful antibiotics (Fleming 1929; Debono, Abbott et al. 1988; Nam et al. 2013) since alternative strategies such as metagenomics, combinatorial biosynthesis and fragment-based drug design have yet to yield large numbers of novel chemical entities with antimicrobial activity. It was estimated that natural products from only bacteria account for half of all commercially available pharmaceuticals (Stewart, 2012). Both culturable and unculturable bacteria from diverse environmental sources have potential to produce antimicrobial compounds. New cultivation strategies using diffusion chambers to mimic the natural enviromnent have been devised to coax uncultured bacteria to grow (Ling et al. 2015). A new class of antibiotic, teixobactin, was recently discovered by screening 10,000 soil bacteria using this approach (Ling et al. 2015). Though the majority of bioactive natural products have been found in soil-borne

bacteria especially from actinomycetes, other environment such as marine ecosystem is a promising source of novel antibiotic producers.

Bacteria from the phylum *Actinobacteria* are the most prominent source for clinically important antibiotics (Baltz 2007). Among them microorganisms belonging to the order Actinomycetales are fascinatingly diverse for their ability to produce biologically active secondary metabolites. It has been estimated that the order Actinomycetales has yielded ~3000 antibiotics since after its first reporting of streptomycin in 1942 (Waksman et al. 1941; Watve et al. 2001). The genus *Streptomyces* itself produced about 90% of these antibiotics including cephalosporins, chloramphenicol, neomycin, erythromycin, tetracycline, novobiocin, vancomycin, kanamycin, fosfomycin and daptomycin (Watve et al. 2001; de Lima Procópio et al. 2012). It has also been reported that *Streptomyces* spp. have the ability to synthesize important antifungal (amphotericin B) (Caffrey, Aparicio et al. 2008), anticancer (mitomycin C) (Olano, Mendez et al. 2009), antiparasitic (ivermectin) (Nett et al. 2009) and immunosuppressive (rapamycin) agents (Graziani 2009).

Single species of *Streptomyces* can produce several antibiotics and antibiotic profile is specific to each species. *Streptomyces coelicolor* is the model species of this genus produces at least five different antibiotics including two pigmented antibiotics actinorhodin and undecylprodigiosins, as well as a polyketide cryptic polyketide, a calcium-dependent ionophore antibiotic, and an unusual cyclopentanone antibiotic methylenomycin (Liu et al. 2013). David A. Hopwood was the pioneer of the *S. coelicolor* genetic studies (Chater, 1999; Ruddy et. al. 1979; Hopwood, 2006) provided the first evidence that the genes for biosynthesis of any particular antibiotic are clustered on the chromosome or in plasmids (Rudd et al. 1979; Ruddy et al. 1980). *S. coelicolor* has a complex life cycle consisting of the substrate or vegetative mycelium to the

formation of sporulating aerial hyphae. The germination of spores occurs in the presence of soluble nutrients, and when nutrients begin to run out, an aerial mycelium forms. Autolysis of the vegetative and substrate mycelium generates energy for the aerial growth. Antibiotic production usually takes place at this stage when nutrient concentration is limited. Antibiotic production might provide protection for the nutrients being released or against invaders (Chater et. al. 1979).

Complete genome sequence of *S. coelicolor* strain A3(2) (Bentley et al. 2002) revealed that the organism has a linear chromosome of 8.6Mbp encoding 7,825 predicted genes with more than 20 known or predicted secondary metabolites biosynthesis gene clusters (Bentley et al. 2002). These clusters are generally large and usually contain several operons. Genome mining also revealed that large portion of the genome is dedicated to encode regulatory genes that control physiology, developmental state, population density, and the level of antibiotic production. Detailed molecular analysis of sequenced genes of *S. coelicolor* demonstrated the complex developmental inter play of antibiotic production with morphological differentiation providing information for increased level of antibiotic production and also suggested ways to activate silent genes for its production. The physiological signals and regulatory mechanisms play important roles in the activation of many cryptic secondary biosynthetic gene clusters thus understanding these mechanisms will unleash the full biosynthetic potential of this organism. The proposed methods for activating cryptic gene clusters in *Streptomyces* include manipulation of fermentation conditions, genome mining, genetic manipulation of the regulatory gene clusters, regulation of signaling molecules, ribosome engineering and heterologous expression of gene clusters (Liu et al. 2013).

Antibiotic production is dependent on a number of nutritional factors including efficient sources of carbon, nitrogen, phosphate, several metals such as zinc, iron, and manganese (Coisne et al. 1999; Owen et al. 2007). In addition to nutritional effects, the pH, temperature and dissolved oxygen level are also important for antibiotic production (Desai et al. 2002).

In addition to *Streptomyces*, other *Actinobacteria* including *Nonomuraea* produce secondary metabolites with antimicrobial activity (Cornaglia et a. 2009). For instance, *Nonomuraea* sp. ATCC 39727 produces the teicoplanin-like glycopeptide antibiotic A40926 which is a precursor for semi-synthetic derivative dalbavancin, an antibiotic that is currently approved by FDA for treating MRSA infections. The genus *Nonomuraea* was described by Zhang et al. (Zhang et al. 1998) based on spore formation and 16S rRNA gene sequences. The genus comprises 27 species and *Nonomuraea pusilla* is the type species (Zhao, Li et al. 2011). The members of this genus can be isolated from diverse natural habitats including soil, plants, caves, marine and river sediments (Nakaew, Sungthong et al. 2012). Like most *Actinobacteria*, *Nonomuraea* spp. also produce various shades of blue, violet, red, rose, yellow, green, brown and black pigments on natural and synthetic media, and the pigments maybe dissolved into the medium or it may be retained in the mycelium. The pigments produced from *Actinobacteria* have been used on cotton shades (Perumal, Stalin et al. 2009) and in medicine, pharmacology and cosmetic preparations (Perumal, Stalin et al. 2009). Moreover, several reports indicated that antimicrobial activities and/or antibiotic production of *Actinobacteria* are associated with pigment production (Miyaura and Tatsumi 1961). Watve et al (Watve, Tickoo et al. 2001) estimated that members of this phylum potentially produce around 100,000 antimicrobial metabolites, and this estimate demonstrates that only a small percentage of the extant antibiotics that have already been

discovered. To discover the vast number of remaining antibiotics, we need to get access to a greater diversity of bacteria.

Members of other bacterial phyla including *Firmicutes, Bacteroidetes* and *Proteobacteria* are well known to be a prolific source of bioactive natural products (Hamdache et al. 2011; Stein 2005; Figueiredo et al. 2011). Within these diverse bacteria, the genus *Bacillus* represents particular interest in terms of its ability to produce wide range of natural products with potential antimicrobial activity. The species of genus *Bacillus* is common in soil and plays an important role in plant growth as they are considered to be a member of plant growth-promoting rhizobacteria (PGPR). The PGPR bacteria can promote plant growth directly by helping plants acquire nutrition from soil, or indirectly by controlling phytopathogens to prevent plant diseases (Kloepper et al. 1980). Application of PGPR results in significant enhancement of plant growth and increased yields of agronomically important crops. PGPR produce different types of metabolites that include antibiotics (Fuller, Mellows et al. 1971), cell wall- degrading enzymes (Ramos-Solano, Lucas García et al. 2010), sidorophores (Kloepper, Leong et al. 1980) and HCN (Askeland and Morrison 1983). A wide variety of antibiotics that include polyketides, heterocyclic nitrogenous compounds, phenylpyrrole, cyclic lipopeptides, noncyclic lipopeptides and aminopolyols are also produced by PGPR strains (Fernando, Nakkeeran et al. 2006).

The majority of antibiotics produced by *Bacillus* spp. are low molecular weight polypeptides that are synthesized by ribosomal or non-ribosomal mechanisms. Surfactins, iturins, fengycins macrolactins, difficidins and lantibiotics are major antibiotics that are produced by *B. subtilis* (Hamdache et al. 2011; Stein 2005; Sumi et al. 2014). In addition to antibiotic production, *Bacillus* spp. can be used as probiotics in animals and plants for growth promotion and disease control (Ran et al. 2012; Ahmed et al 2014; González-Ortiz et al. 2013).

The beneficial effects of probiotics include antagonism to pathogens, enhancement of immune response and restoration of the body's normal microflora (Sun et al. 2010; Casula et al. 2002). Many *Bacillus* strains from species *B. clausii, B. cereus, B. pumilus* and *B. amyloliquefaciens* are currently being used as probiotic strains for human nutrition, as animal feed supplements and in aquaculture (Krober et al. 2014; Lee et al. 2012; Verschuere et al. 2000; Larsen et al. 2014). Probiotics contain live microorganisms that, when administered in adequate amounts (e.g., in case of *Bacillus* a single dose contains up to 10^9 spores/g or 10^9 spores/ml), confer a health benefit on the host (Duc et al, 2004; Sanders, 2008). Probiotics are generally taken as a prophylactic agents, but their application as therapeutic agents has also been described in literature (Mazza, 1994). However probiotics are used, the following three basic mechanisms are involved their beneficial effects: 1) secretion of antimicrobial compounds which inhibit the growth of pathogens, 2) competitive exclusion of pathogens (e.g., competition for adhesion sites), and 3) immunomodulation (e.g., stimulation of lymphocytes and induction of cytokines). The ability of probiotic *Bacillus* strains to produce antimicrobial agents is well documented and more than 80 different types of antimicrobial compound have been identified from different *Bacillus* species (Mazza, 1994). These antimicrobial agents can completely inhibit the growth of pathogenic bacteria or contribute to the competitive exclusion of pathogens. The immune stimulation mechanism of probiotic involves in induction of proinflammatory cytokines that increase phagocytosis of pathogens (by macrophages or dendritic cells) and also stimulation of B cells and cytotoxic T cells. Duc et al. (Duc et al. 2004) demonstrated that *Bacillus* spore is immunogenic, producing 10-fold higher spore-specific IgG responses when mice were orally administered with Biosubtyl^{NT} , a strain of *B. pumilus*. *In vivo* cytokine expression profile revealed the production of TNF-α and IFN-γ in the secondary lymphoid organs and gut

associated lymphoid tissue of mice after inoculation of probiotic (Duc et al. 2004). However, in their *in vitro* assay *TNF-α and IL-1α* were absent instead they found proinflammatory cytokine IL-6. Together, these inflammatory responses enhance the innate immune system and activate macrophage for phagocytosis after application of probiotic. Similar results were observed when probiotic *Lactobacillus* species were administered orally (Schiffrin et al. 1995).

Although probiotic use of *Bacillus* for growth promotion and prevention of gastrointestinal infection has been studied extensively, the probiotic effect of *Bacillus* strains against MRSA has not been previously explored. Therefore, exploring *Bacillus* spp. for identifying active compounds with anti-MRSA activity and their potential use as a probiotic to prevent skin colonization by MRSA will be of special interest.

1.11.2 Culture-independent approach to discover antibiotics

Prokaryotes are the most abundant biological entities in soils (except perhaps viruses) and comprise most of the soil biomass (Hassink, Bouwman et al. 1993). The metabolic and functional versatility of soil microorganisms makes this environment a good source for the discovery of novel natural products, including antibiotics (Marcia S. Osburne, Trudy H. Grossman et al. 2000). A vast number of antibiotics in use today to treat patients with infectious diseases are derived from soil bacteria or fungi (Newman and Cragg 2007). However, only a small fraction of the environmental microbes has been successfully explored for natural product discovery (Thomason et al. 2007) indicating that a wealth of microbial diversity still exists in nature and the remaining untapped natural product diversity offers tremendous potential for discovering novel therapeutics. A recent strategy for antibiotic discovery is metagenomic analysis of uncultured microbes.

Metagenomic libraries are constructed by extracting environmental DNA (eDNA) directly, allowing analysis of the collective genomes of all the resident organisms (Yadav et al. 2003; Kapur et al. 2008). Any environmental source such as soil (Sangwan, Lata et al. 2012), sediments (Havelsrud, Haverkamp et al. 2011), activated sludge (Liaw, Cheng et al. 2010), and hot thermal vent sediments (Wemheuer, Taube et al. 2013) can be used for the isolation of genomic DNA for metagenomic studies. However, isolation of high molecular weight (HMW) DNA from environment is always a significant issue due to the inherent conflict between the need to recover DNA from diverse microorganisms while preserving DNA integrity. A significant progress has been made for isolation of high quality of DNA from diverse environmental samples (Liles et al. 2008; Voget et al. 2006; Stein et al. 1996; Abulencia et al. 2006; Uchiyama et al. 2005; Rhee et al. 2005). The isolated eDNA fragments then directly cloned into a vector and the resulting cloned libraries can be investigated for the microbial diversity analysis and drug discovery.

To construct a metagenomic library, eDNA fragments can be cloned into plasmid, cosmid, fosmid or BAC (Bacterial Artificial Chromosome) vector. These cloning vectors have limitation for example plasmid, cosmid and fosmid vectors can carry only small fragments of DNA: plasmids, <20 kb; cosmids, 37 - 52 kb; and fosmids, <42 kb. However, BAC vector can carry longer DNA fragments of up to 300 kb (Wang et al. 2014). This is particularly advantageous since many of the bioactive compounds (e.g. antibiotics, multimodular polyketide, or nonribosomal peptide) are encoded by a gene cluster whose length typically exceeds beyond the limits of DNA sizes carried by a plasmid, cosmid, or fosmid vector (Piel, 2011). Other advantages of BAC clone libraries include screening a smaller number of BAC clones to identify desired cluster and stability of metagenomic DNA fragments in the BAC vector. However, BAC

libraries are technically more difficult to construct than other types of clone libraries, the choice of the vector depends on the DNA quality, targeted genes, and library screening strategy (Daniel, 2005).

A metagenomic library can be screened by functional screening and sequence based screening. Recent advancement of next-generation sequencing techniques allows large-scale analysis of microbial communities with novel applications. Sequence-based screening is a widely used approach to find genes or gene clusters involved in particular functions within a metagenomic library. Sequence-based screening first identify clones that contain know pathways for secondary metabolites and then express these pathways in a suitable host for activity. This method allows to identify novel analogs of known metabolites. Sequence-based screening has led to the successful identification of pathways and genes that encode novel enzymes, such as type II polyketide synthases (PKS) biosynthetic pathway was first identified in cosmid clones (Feng et al. 2011), discovery of new pentangular polyphenols including calixanthomycin A, arenimycins C and D with antiproliferative and antibacterial activity respectively (Kang et al. 2014), and several enzymes including nitrite reductases (Bartossek et al. 2010), glycerol dehydratases (Knietsch et al. 2003), chitinases (Hjort et al. 2010). The first bacterial proteorhodopsin, a light-driven proton pump, was also discovered by sequence analysis of specific BAC clones containing 16S rRNA gene sequence and other essential genes for function (Beja et al.2000). Though sequence-based screening showed potential to discover novel compounds and pathways, large-scale metagenomic projects are limited with respect to data handling, data integration and data analysis.

Though there are a number of outstanding challenges in functional metagenomics such as 1) the insert size of the library, 2) efficient screening methods for the massive libraries generated,

and 3) barriers to heterologous gene expression in the host species (Uchiyama et al. 2009) which can limit natural product discovery, functional metagenomics is still the only strategy that bears the potential to identify entirely novel classes of genes encoding known or novel functions.

The functional diversity of metagenomic clones can be determined phenotypically and in most cases, phenotypical detection employs by applying an indicator substrate of the enzymes of interest into the growth medium, where it confers the specific metabolic capabilities of individual clones. The active clones can be detected by visual inspection of an indicator agar plate, by flow cytometry, a spectrophotometer, or fluorescent microtitre plate readerdepending on the assay type (Taupp et al. 2011).

Enzymatic activities expressed by metagenomic clones can be identified by function-based screening. The active clones can be detected via many different methods, including colorimetric or fluorescent assays, as well as indicator media (Taupp et al. 2011). For example, lipase-producing BAC clones were identified using 1.0% tributyrin on LB agar plates. Tributyrin hydrolysis forms a halo around clones which can produce lipase enzyme. Other enzymes identified from BAC clones include cellulase, xylanase, esterase, alcohol dehydrogenase, amidase, amylase, protease, chitinase, dehydratase, and β-lactamase (Lorenz et al. 2005).

Identification of secondary metabolites with antimicrobial activities using functional metagenomic approach is well documented such as isolation of turbomycin A and B (Gillespie et al. 2002), the identification of antibacterial activities expressed in cosmid libraries in different proteobacterial hosts (Craig et al. 2010), identification of gene clusters involved in synthesis of antifungal activities (Chung et al. 2008) and identification of anticancer agent (Pettit 2004; Banik and Brady 2010). MacNeil et al (MacNeil et al. 2001) isolated a small molecule, called indirubin,

from a soil metagenomic library and later it was found that indirubin and its derivatives inhibit tumor growth by antitumor angiogenesis (Zhang et al. 2011; Shin et al. 2012).

The selection of a host for cloning, maintenance and screening of a metagenomic library influences the success of the metagenomic project since functional expression of genes from an environmental source might be limited due to the application of a single heterologous host. *E. coli* is the most widely used host for expressing metagenomic libraries, due to the ease of cloning DNA but not necessarily improved expression of metagenomic DNA. Other bacterial heterologous hosts may include *Streptomyces*, *Agrobacterium tumefaciens*, *Burkholderia graminis*, *Caulobacter vibrioides*, *Pseudomonas putida*, or *Ralstonia metallidurans*, all of which have been used for the discovery of natural products from soils using a functional metagenomic approach (Wang, Graziani et al. 2000; Craig et al. 2010).

Chapter 2

Isolation of novel soil *Actinobacteria* that express antibacterial activity against methicillin resistant *Staphylococcus aureus*

1. Abstract

The emergence of multidrug-resistant pathogens has increased the demand for discovery of novel antibiotics. Soil microbial communities are a great resource for natural products but a majority of them have not been explored due to the recalcitrance of many bacterial taxa to laboratory cultivation. We isolated a collection of 548 bacterial and fungal isolates from soil using low-strength (1/200th) nutrient agar supplemented with soil extract incubated for more than three months at room temperature. Bacterial diversity analysis using 16S rRNA gene sequences of newly cultured isolates revealed that they represent diverse bacterial genera affiliated with the phyla *Acidobacteria*, *Actinobacteria*, *Bacteroidetes*, *Firmicutes*, and *Proteobacteria*. Two isolates, designated as A115 and F4, were found to inhibit the growth of pathogenic methicillin-resistant *Staphylococcus aureus* (MRSA). The isolate A115, member of the genus *Streptomyces*, produces pink pigments after incubation for more than ten days. The isolate F4, identified as a *Nonomuraea* spp., produces a high molecular weight (>100kDa), heat stable reddish pigment associated with anti-MRSA activity. Genome sequencing using a combination of shotgun and mate-pair next-generation sequencing resulted in the complete assembled genome for each isolate, with the size of the A115 and F4 genomes at 8.6 Mb and 10.3 Mb, respectively. The %G+C contents of strains A115 and F4 were determined to be 71% and 70.4%, respectively. Phylogenetic analysis using multilocus sequence analysis with six housekeeping genes revealed that strain A115 was most closely related to *Streptomyces afghaniensis* and *Streptomyces olindensis*; however, the low level of average nucleotide identity (ANI) values in comparing the

A115 genome were 89.76% and 89.14% for *S. afghaniensis* and *S. olindensis*, respectively. These genomic results, combined with differentiation of strain A115 from other *Streptomyces* species by morphological and physiological characteristics, led to the conclusion that strain A115 represents a novel species of the genus *Streptomyces*, for which the name *Streptomyces alburnustigris* sp. nov. is proposed. Phylogenetic analysis based on 16S rRNA gene sequence revealed that the closest phylogenetic relative of F4 strain was *Nonomuraea antimicrobica* YIM 61105. *In silico* analysis using anti-SMASH predicts that the A115 and F4 genomes encode many gene clusters for secondary metabolite biosynthesis, including the synthesis of terpene, aminoglycoside, thiopeptide, bacteriocin, oligosaccharide, phenazine, butyrolactone, siderophore, melanine and potentially other bioactive compounds produced by non-ribosomal peptide synthetase and polyketide synthetase pathways. Both *S. alburnustigris* A115 and *Nonomuraea* spp. strain F4 genomes are predicted to encode Type I, II, and III PKS pathways. The biochemical structure of the active anti-MRSA compounds are currently being characterized using liquid chromatography–mass spectrometry (LC/MS). This study identified novel bacterial isolates with anti-MRSA activity and demonstrates the utility of novel cultivation techniques in obtaining previously uncultured and phylogenetically diverse soil microorganisms, some of which express potent bioactive secondary metabolites.

2. Introduction

The phylum *Actinobacteria* is comprised of diverse Gram-positive taxa that have a high %G+C content and exhibit varied morphologies, physiologies, and metabolic properties such as the production of extracellular enzymes and the synthesis of a wide variety of secondary metabolites. Members of *Actinobacteria* have very diverse lifestyles, ranging from pathogens (e.g., *Corynebacterium*, *Mycobacterium*, *Nocardia*, *Tropheryma*, and *Propionibacterium*) to

antibiotic-producing soil inhabitants (*Streptomyces*, *Nonomureae*) and plant commensals *(Leifsonia*), or gastrointestinal commensals (*Bifidobacterium*). Furthermore, they adopt complex life cycles that consist of vegetative growth followed by the formation of aerial hyphae and finally exospore formation. Spore formation allows them to disperse and persist in diverse environmental niches. Most members of this phylum are ubiquitous in terrestrial and aquatic ecosystems and play an important role in the production of natural products with pharmaceutical applications and recycling of organic matter by decomposition.

Actinobacteria constitute a significant portion of soil microflora, estimating that a gram of fresh soil contains about 10^9 CFU/g of bacteria and of which 10^7 are *Actinobacteria* taxa (Steffan et al. 1988; Weinbauer et al. 1998). Therefore, diverse soil samples can be an overwhelmingly rich reservoir for discovering of bioactive compounds. The microorganisms belonging to the order Actinomycetales are fascinatingly diverse for their ability to produce biologically active secondary metabolites. It has been estimated that the order Actinomycetales has yielded ~3000 antibiotics since after its first reporting of streptomycin in 1942 (Waksman and Woodruff 1941; Watve, Tickoo et al. 2001). The genus *Streptomyce*s itself produced about 90% of these antibiotics including vancomycin, erythromycin and tetracycline (Watve, Tickoo et al. 2001). It has also been reported that *Streptomyces* spp. have the ability to synthesize important antifungal (amphotericin B) (Caffrey, Aparicio et al. 2008), anticancer (mitomycin C) (Olano, Mendez et al. 2009), antiparasitic (ivermectin) (Nett, Ikeda et al. 2009) and immunosuppressive (rapamycin) agents (Graziani 2009).

In addition to *Streptomyces*, some rare *Actinobacteria* including *Nonomuraea* (Tiwari et al. 2012) can be potential producers of secondary metabolites with antimicrobial activity (Cornaglia and Rossolini 2009). For instance, *Nonomuraea* sp. ATCC 39727 produces the

teicoplanin-like glycopeptide antibiotic A40926 which is a precursor for semi-synthetic derivative dalbavancin, an antibiotic that is currently in clinical use (Boucher et al. 2014). Like most *Actinobacteria*, *Nonomuraea* spp. also produce various shades of blue, violet, red, rose, yellow, green, brown and black pigments on natural and synthetic media and the pigments maybe dissolved in to the medium or it may be retained in the mycelium. The pigments produced from *Actinobacteria* have been used on cotton shades (Perumal, Stalin et al. 2009) and in medicine, pharmacology and cosmetic preparations (Perumal, Stalin et al. 2009). Moreover, several reports indicated that antimicrobial activities and/or antibiotic production of *Actinobacteria* are associated with pigment production (Miyaura and Tatsumi 1961). It has been estimated that (Watve, Tickoo et al. 2001) members of this phylum can potentially produce around 100,000 antimicrobial metabolites and this estimate demonstrated that only a small percentage (~3%) of the extant antibiotics that have already been discovered (Watve et al. 2001). To discover the remaining antibiotics, we need to get access to a greater diversity of bacteria. Those diverse bacterial sources can be tapped for antibiotics by expanded conventional culturing approach, novel culture methods, heterologous DNA-based methods and metagenomics.

The discovery of new antibiotics using a culture-based approach is still the most historically successful approach (Fleming 1929; Debono, Abbott et al. 1988; Jang, Nam et al. 2013), since alternative strategies such as metagenomics, combinatorial biosynthesis and fragment-based drug design have yet to yield large numbers of novel chemical entities with antimicrobial activity. However, although there has been a wealth of antibiotics discovered from cultured soil microbes (Thiele-Bruhn 2003), the past several decades have experienced diminishing success rates for antibiotic discovery using a culture-based approach. This is due to the very high rate of antibiotic re-discovery (>99%) when screening cultured bacteria grown

under “normal” laboratory conditions, i.e. high nutrient levels with short incubation times. Culture-based approaches have recently gotten new momentum due to technology advancements such as employing novel culturing techniques, i.e. low-nutrient media with extended incubation time (Hamaki et al. 2005) or use of a multichannel device iChip for simultaneous isolation and culturing of as-yet unculturable bacteria (Ling et al. 2015), applying next-generation sequencing and high-throughput screening (Baltz 2008).

The recent advancement of genome sequencing technologies has revealed that actinomycetes have a much greater potential for secondary metabolite production than first assumed. Complete genome sequences of available *Actinobacteria* indicated that they contain many more secondary metabolite biosynthetic gene clusters than the number of actually identified metabolites would suggest. Genome mining revealed that a single isolate has the genetic potential to synthesize more than one secondary metabolite; however, the probability of discovering a novel compound can be far greater if unique isolates are screened simultaneously. Thus, in this research project a combination of selective isolation and screening procedures for the collection of novel and/or rare Actinobacteria from unexplored soil samples were used for discovery of novel compounds with antibacterial activity against methicillin resistant *Staphylococcus aureus*.

3. Materials and methods

Collection of soil samples

To isolate soil microorganisms with antibacterial activity against clinical MRSA strain, soil samples were collected from three different sources including the Cullars Rotation, the Auburn University Arboretum and a long-leaf pine forest sample that represented three characteristic soils in the State of Alabama. The Cullars Rotation has a sandy agricultural soil

and for this study, the soil sample was collected from a soil plot that had not been amended with fertilizers for the past 100 years. Soil from Arboretum was the Black Belt soil which is very rich and alkaline in nature, and contained a considerable amount of montmorillonite clay. The forest soil obtained from Long Leaf Pine forest at Auburn contained high clay abundance characteristic of many Appalachian soils. All samples were collected from the top 10-cm layer of soil, homogenized, and sieved to eliminate plant roots and other debris. Soil samples were diluted in sterile water and extracts were plated immediately into 1/200 strength Nutrient Agar (NA) plates after sampling.

Cultivation of soil microorganisms

Soil microorganisms were isolated based on the method described previously (George et al. 2011). Briefly, two types of solid media were used for the cultivation of soil microorganisms: 1) dilute nutrient broth (0.065g/L) which is 200 times diluted than the manufacturer's instructions ($1/200^{th}$ NA) supplemented with 15 g/L agar; and 2) $1/200^{th}$ diluted nutrient agar (NA) supplemented soil extract (SE) ($1/200^{th}$). The soil extract was prepared from three soil samples according to the protocol described by (George et al. 2011). To cultivate soil microorganisms, 1.0 g of soil from Cullars rotation, arboretum or long-leaf pine forest was added into 99.0 mL of sterile milliQ water and stirred for 2 hours at 200 rpm. After settling for 1 hour, the supernatant was serially diluted up to 10^{-7} dilutions and aliquots of 100 µL of each dilution were spread onto $1/200^{th}$ NA and $1/200^{th}$ NA+SE plates with 4 replicates per dilution. Plates were incubated for up to 3 months at room temperature (approximately 22°C). After incubation, each colony was subcultured onto $1/200^{th}$ and $1/100^{th}$ diluted NA plates in duplicates. Each isolate was then subjected for phylogenetic analysis using 16S rRNA gene sequences and screening for antibacterial activity against clinical MRSA strain 30.

Phylogenetic analysis of soil isolates

Each of the pure culture isolate grown on 1/200th NA was subjected to phylogenetic analysis using 16S rRNA gene-specific sequences. Colony PCR was performed on each individual colony with universal bacterial primers 27F and 1492R which generated approximately 1.5 kb products. PCR reactions were performed in 50 µL reaction volumes which contained 25.0 µL of 2× EconoTaq plus Green DNA Polymerase (Lucigen Co. WI), 0.2 µM of each primer and sterile nuclease free water for adjusting to 50 µL. Amplification of the 16S rRNA gene was carried out under the following conditions: denaturation at 94°C for 2 min followed by 35 cycles of 94°C for 30 s, 55°C for 30 s, 72°C for 2.0 min and final extension at 72°C for 10 min. Amplified PCR products of bacterial isolates were analyzed by electrophoresis with 0.7% agarose gel run at 200V for an hour. After electrophoresis gel was stained by ethidium bromide and then visualized and photographed under UV transilluminator, Gel Doc XR system (Biorad USA). The PCR products were purified by E.Z.N.A cycle pure kit (Omega bio-tak USA) according to the manufacturer's instructions and purified PCR products were then sequenced in both directions using primers 27F and 1492R (Lucigen Corp, Middleton, WI USA). The sequences were trimmed for quality using ChromasPro (Technelysium, Australia). Trimmed sequences were then assembled and compared against sequences available in the National Center for Biotechnology Information (NCBI data base), Genbank, using the BLASTn algorithm.

Isolation of soil microorganisms with antibacterial activity

The antibiosis assay was carried out by double-layer soft agar method with minor modifications (Jack et al. 1996). Briefly, each of the soil microorganisms were grown on 1/200th NA plates for 3 months at room temperature. After incubation, soft agar (0.7% w/v agar) was

prepared with NA was melted, cooled and seeded with a freshly prepared inoculum of log-phase MRSA strain 30 to achieve the absorbance at 600 nm (OD_{600}) of 0.5. The bacterial cell suspension in soft agar was immediately poured over the $1/200^{th}$ NA plates and incubated for 24 hours at 37°C. After incubation, the presence of zones of inhibition in the growth of MRSA strain 30 were recorded (in mm) as evidence of growth inhibition caused by soil isolates. Soil bacterial isolates that inhibited the growth of MRSA strain 30 were subcultured on to $1/200^{th}$, $1/100^{th}$, $1/50^{th}$, and $1/10^{th}$ NA and nutrient broth (NB) for further analysis.

To verify the anti-MRSA activity, all soil isolates that showed antibacterial activity in primary screen were re-tested via drop assay. In this assay soil isolates that showed antibacterial activities against MRSA strain 30 from the preliminary selection were grown in $1/10^{th}$ NB for one month at room temperature. After incubation, supernatants were collected and frozen for further analysis. A broth culture of actively growing MRSA strain 30 was adjusted to OD_{600} of 0.5 and evenly swabbed onto TSA plates. Then 10 µL of supernatants derived from soil cultures were added onto the MRSA strain 30 culture. Zones of inhibition were measured after 24 hours of incubation at 37°C. The soil isolates which showed repeated antibacterial activities in drop assay were selected as positive isolates and maintained the cultures in $1/10^{th}$ NB for further experiments. An aliquot of supernatants obtained from each soil isolates were also shipped to the National Center for Natural Products Research (NCNPR), the University of Mississippi for screening against a larger collection of bacterial and fungal pathogens.

Antibacterial activity of *Streptomyces* sp. strain A115 and *Nonomuraea* sp. strain F4

The effect of incubation time and concentrations of A115 and F4 supernatants on the growth of MRSA strain 30 was determined by the microtiter plate assay as described previously (Rufián-Henares et al. 2008). Both A115 and F4 isolates were grown in 10 mL of $1/10^{th}$ NB at room temperature. Each week 2 mL of A115 and F4 supernatants were evaluated for anti-MRSA activity by using double dilution method. For antibacterial assay, the overnight culture of MRSA strain 30 was diluted 1:100 into a fresh broth and incubated further (~2 to 3 hours) to achieve absorbance at 600 nm (OD_{600}) of 0.5 which are equivalent to 1.4×10^8 CFU/mL. Then 50µL of bacterial cell suspension was inoculated into a sterile 96-well microtiter plate containing A115 or F4 supernatant and plates were incubated for 24 hrs at 37°C. Turbidity of MRSA strain 30 was measured as absorbance at 600 nm by Gen5 spectrophotometer (BioTek Instruments, VT, USA).

Extraction of anti-MRSA compounds

Two of the bacterial isolates *Streptomyces* sp. A115 and *Nonomuraea* sp. F4 with anti-MRSA activity were grown in $1/10^{th}$ NB at room temperature for one month. The active supernatant of A115 isolate was collected by centrifugation followed by filtration. Filtered supernatants were stored at -80°C and an aliquot of the supernatant was sent to the National Center for Natural Product Research (NCNPR, Oxford, MS) according to the standard protocol established by the NCNPR for determining the biochemical structure of the active compound(s) and further screening against a large collection of bacterial and fungal pathogens. The active supernatant of F4 isolate was extracted with five different amberlite resins including XAD-4, XAD-7, XAD-16, XAD-1180N and an anionic resin DE52 (Sigma-Aldrich, USA). For separating active compound(s), a 25 mL syringe was packed with approximately 8 g of XAD resin. Then 50 mL of F4 supernatant was passed through the XAD column and then column was

washed 3 times with water. Finally, adsorbed compounds were eluted with 90% ethanol and 10% acetic acid. Ten fractions with approximately 10 mL of each were manually collected followed by concentrated with Vacufuge (Eppendorf, USA). Each concentrated (500×) fraction was tested for Anti-MRSA activity before they were analyzed by HPLC method. The active fractions were separated by HPLC and each fraction was tested separately or pooled together for anti-MRSA activity.

Morphological characteristics of anti-MRSA compound producing soil bacteria

Morphological characteristics of *Streptomyces* sp. A115 and *Nonomuraea* sp. F4 were examined using light and scanning electron microscopy of colonies grown on $1/10^{th}$ NA and $1/10^{th}$ NB after incubated for 21 days at room temperature. For high-resolution scanning electron microscopy, a colony with agar or 10 µL of bacterial suspension was added onto a double sided sticker coated aluminum stubs and dried completely by air drying. The dried samples were coated with gold alloy by a 108 Auto/SE Sputter Coater (Cressington EM Vacuum Coating Systems, USA), and examined with a Zeiss EVO 50VP (Germany) scanning electron microscope.

The colony morphology and anti-MRSA activity of strains A115 and F4 were observed on several standard media that included i) International Streptomyces Project 4 (ISP 4), ii) ISP 2 supplemented with 5% NaCI, iii) $1/10^{th}$ NA supplemented with 0.2% N-acetylglucosamine, iv) $1/10^{th}$ NA with or without 1.5% NaCI, v) SYZ media with or without artificial sea water, vi) R2YE (Shepherd et al. 2010) and vii) modified YEME media (Shepherd et al. 2010) after 21 days of incubation at room temperature.

Biochemical and physiological characteristics of actinobacterial strains A115 and F4

Biochemical and physiological characteristics of the actinobacterial isolates A115 and F4 were determined based on the method described previously (Shirling et al. 1966). Biochemical tests including Gram's reaction, MR-VP, H_2S production, nitrate reduction, oxidase, catalase, urease, blood hemolysis, TSI, citrate utilization, starch, casein and gelatin hydrolysis were performed as protocol described by Meena et al. (Meena et al. 2013). Ability of the isolates to utilize various carbon sources, i.e. sucrose, lactose, glucose, ribose, xylose, mannitol, maltose, arabinose, raffinose and salicin were performed in ISP-2 agar medium with phenol red as an indicator (Biehle et al. 1996). Physiological characteristics such as tolerance to salt (5-30% NaCl), pH (5–11) and survival at 25-45°C with and without shaking of isolates A115 and F4 were also examined. Strains A115 and F4 were grown in $1/10^{th}$ NB and incubated on a rotatory shaker at 85 rpm at room temperature for 21 days. Cells were harvested by centrifugation at 8000rpm for 10 mins. Aliquots of cell pellets were shipped to MIDI labs for whole cell fatty acid profiling.

Genetic characterization of actinobacterial isolates

Isolation of genomic DNA

Actinobacterial isolates A115 and F4 were grown in 500 mL of $1/10^{th}$ nutrient broth for 25 days at room temperature before cells were harvested by centrifugation. Genomic DNA was extracted according to the protocol described previously (Nikodinovic et al. 2003) with modifications. Briefly, the cell pellets were collected by centrifugation and pellets were crushed five times with liquid nitrogen. After crushing, the pellets were resuspended in 10 mL of TE buffer which contained 150mg of lysozyme and 50mg of achromopeptidase (Wako chemicals USA). Cell pellets were mixed thoroughly and incubated at 37°C for 4 hours. Then 1.0 mL of

10% SDS and 100 mg of proteinase K (Sigma-Aldrich USA) were added into the suspension and incubated at 55°C for an hour. Tubes were shaking in every 15 min. An equal volume of phenol:chloroform:isoamyl alcohol (25:24:1) was added and the resulting suspension was mixed thoroughly before spinning at 10,000 rpm at 4°C for 10 min. The aqueous phase was collected into a fresh tube and 0.6 volume of isopropanol was added to precipitate the DNA. Shake the tube back and forth until a stringy white DNA precipitate becomes clearly visible. DNA was collected by centrifugation at 12,000 rpm at room temperature for 10 min. The DNA pellet was washed with 70% ethanol and dried the pellet using vacufuge concentrator (Eppendorf USA). Re-suspended the pellet with 10 mL of TE buffer containing 100 μL of RNase A(10 mg/mL) and incubated the solution at room temperature for 30 minutes. Re-extracted DNAs with an equal volume of phenol: chloroform: isoamyl alcohol (25:24:1), after mixing thoroughly the DNAs were collected by centrifugation at 10,000 rpm at 4°C for 10 min. The aqueous phase was transferred into a fresh tube and $1/10^{th}$ volume of 3M Na-acetate (pH 5.2) and 2.5 volume of 100% ethanol were added. Resulting solution was incubated at -20°C for 30 min prior to collecting the DNA pellet by spinning at 12,000 rpm for 10 min at 4°C. The pellet was washed with 70% ethanol and dried the pellet using Vacufuge concentrator. After drying, the pellet was dissolved in 500 μL of nuclease free water and concentration of DNA was measured by using Qubit 2.0 fluoromoter (Life technologies, USA).

Whole genome sequencing, assembly and annotation

To complete the genomes of A115 and F4, long span 10-20 kb NGS mate pair libraries and a conventional 600 bp paired end fragment libraries were constructed at Lucigen Corp. (Middleton, WI). Genomic DNAs of strains A115 and F4 were used to make 8 kb mate-pair

libraries. The library was constructed for Illumina sequencing using a NxSeq® Long Mate Pair Library Kit according to manufacturers protocol (Lucigen, Middleton, WI). The 20 kb Long Mate Pair Libraries were constructed using the NxSeq® Long Mate Pair Library Kit with the 10-20 kb insert Supplementary Protocol (Lucigen). In brief, the 20kb libraries were constructed by shearing genomic DNA to 25 kb with a Covaris G-Tube (15 µg DNA was centrifuged at 3200 rpm in a G-Tube for 8 min in both orientations) followed by end repair, A-tailing and ligation to adaptors. Adapted DNA was then size-selected on a 0.3% SeaKem Gold agarose gel (Lonza, Basel, Switzerland) and eluted with an Elutrap Electrophoresis Chamber (GE Healthcare Life Sciences, Pittsburgh, PA). Size-selected DNA was then ligated to a coupler, exonuclease treated, digested with restriction endonucleases and purified prior to circularization with a junction adaptor and amplification with KAPA HiFi HotStart ReadyMix (Kapa Biosystems, Boston, MA). A115 and F4 fragment libraries were constructed from genomic DNA sheared to 50-1000 bp (peak ~500 bp) by g-Tube (Covaris), using the NxSeq Fragment Library kit (Lucigen, Middleton WI) according to manufacturer's protocol. All libraries were size-selected with Agencourt AMPure XP beads (Beckman Coulter, Inc., Brea CA) and sequenced on an Illumina MiSeq using MiSeq Reagent kit version 3. Genomic sequence assemblies were carried out with SPAdes 3.5 (bioinf.spbau.ru/spades) using a range of Kmer values (22 to 77). Fragment library reads were assembled independently, in combination with 8kb mate-pair library reads, or in combination with both 8kb and 20kb mate-pair library reads. For each genome, the assembly with the largest scaffold(s) and fewest unassigned contigs was imported into CLC Genomics Workbench 7.5 for gap filling and finishing the genome. The remaining gaps in the genomes were closed by Sanger sequencing of PCR amplicons and unscaffolded gaps were closed by sequencing of single-primer PCR amplicons according to the method described previously

(Karlyshev et al. 2000). For annotation of the A115 and F4 genomes, the final closed-circle version of the genome sequences were submitted to the NCBI's Prokaryotic Genomes Automatic Annotation Pipeline (PGAAP) (Angiuoli et al. 2008), followed by submission to GenBank. Gene prediction and annotation were performed using GeneMark (Lukashin and Borodovsky 1998) and RAST annotation server (Aziz, Bartels et al. 2008), respectively. The identity of individual ORFs from secondary metabolite biosynthesis gene clusters was confirmed by BLASTx against the GenBank database.

Prediction of secondary metabolite biosynthesis gene clusters in *Actinobacteria* strains A115 and F4

Secondary metabolite biosynthesis gene clusters for strains A115 and F4 were predicted using the secondary metabolite identification tool antiSMASH3.0 (Blin, Medema et al. 2013). Gene prediction and annotation were carried out by GeneMark (Lukashin and Borodovsky 1998) and BLASTx (NCBI), respectively.

Phylogenetic analysis

The 16S rRNA gene was predicted within the complete genome sequences of isolates F4 and A115 using RNammer (Lagesen et al. 2007), software for ribosomal RNA prediction. For multi-locus sequence analysis (MLSA), sequences specific to 16S rRNA, DNA gyrase subunit B (*gyrB*), RNA polymerase beta factor (*rpoB*), bacterial DNA recombination protein (*recA*), ATP synthase beta subunit (*atpD*) and tryptophan synthase beta subunit (*trpB*) were retrieved from 59 *Streptomyces* strains and *Mycobacterium tuberculosis* strain H37Rv using BLASTn tool available in the NCBI web server. Locus specific sequences were aligned, trimmed and concatenated using CLC Genomics Workbench (version 8.0.1). ClustalW algorithm in MEGA

6.0 was used to align 16S rRNA sequences for phylogenetic analysis. The evolutionary history of the *Nonomureae* and *Streptomyces* isolates that included anti-MRSA isolates F4 and A115, respectively, were inferred using Neighbor-Joining method in MEGA 6.0 (Tamura et al. 2011). The confidence of the evolutionary relationships was assessed using the bootstrap method with 1000 replicates. Similar approaches were taken to reconstruct the phylogenetic tree for concatenated six house-keeping genes of 59 strains of *Streptomyces* species.

Average nucleotide identity (ANI)

The average nucleotide identities (ANI) of anti-MRSA isolate A115 against 40 *Streptomyces* strains were determined using JSpecies (version 1.2.1) (Richter et al. 2009)

Mutagenesis of A115 genome to identify secondary metabolite gene cluster(s) for anti-MRSA activity

To identify the secondary metabolites gene clusters responsible for anti-MRSA activity, the genome of A115 was randomly mutagenized using mariner-based transposon Himar1 according to the methods described by Bilyk et al. (Bilyk et al. 2013). Briefly, the *himar1* transposon was conjugally transferred to strain A115 by mating with *E. coli* strain SM10λpir bearing the plasmid pHTM and pHAM. Randomly transposon mutagenized A115 mutants were screened for the loss of anti-MRSA activity.

4. Results

Isolation and identification of soil bacteria

A total of 548 bacterial and fungal isolates were recovered after incubation of three soil suspensions on $1/200^{th}$ NA and $1/200^{th}$ NA +SE plates. It was observed that the addition of soil

extract to the medium was slightly beneficial to all strains, as CFU counts increased 1.5 to 3.2-fold. Each of the pure culture isolates grown on 1/200thNA was subjected to a phylogenetic analysis using 16S rRNA gene. These bacterial isolates (fungal isolates were not ribotyped) represent diverse bacterial phyla that include *Acidobacteria*, *Actinobacteria*, *Bacteroidetes*, *Firmicutes* and *Proteobacteria*. Bacteria isolated from black belt and forest soils were predominantly affiliated with the class α-*Proteobacteria*, representing 55% and 68% of total isolated bacterial phyla for the Black Belt and Forest soils, respectively (Figure 1 A and C). Whereas bacteria isolated from the Cullars agricultural soil were mostly affiliated with the class γ-Proteobacteria, 32% of isolates were belonged to this phylum (Figure 1 B). It was also noted that the forest soil harbored less diverse bacterial phyla than the soils of black belt and agriculture.

Screening of soil isolates with anti-MRSA activity

Each of the isolates collected from 1/200th NA was screened for anti-MRSA activity using a soft agar overlay. After primary screening, a total of 22 isolates were found to inhibit MRSA growth. These bacterial isolates were tested twice for antibacterial and four of them showed repeated antibacterial activities against multiple MRSA strains (Figure 2). Out of the four soil isolates with anti-MRSA, two designated as C3 and C4 were isolated from agricultural soil, other two isolates as A115 and F4 were recovered from black belt and forest soils, respectively. Phylogenetic analysis based on 16S rRNA gene revealed that isolates C3 and C4 were affiliated with the genus *Burkholderia*, and A115 and F4 were identified as *Streptomyces* sp. and *Nonomuraea* sp., respectively. Unfortunately, two of these bacterial isolates, C3 and C4 were not maintained in culture, but the isolates A115 and F4 have been consistently grown on 1/10th

strength NA and exhibit potent anti-MRSA activity against multiple MRSA strains (Figure 2 and 3).

Antibacterial activities of *Streptomyces* sp. strain A115 and *Nonomuraea* sp. strain F4

Using a double-dilution method, culture supernatants of A115 and F4 were screened for *in vitro* antibacterial activity against MRSA strain 30. The expression of secondary metabolites active against MRSA during a time course of bacterial growth was determined and it was found that both A115 and F4 express detectable anti-MRSA compounds as early as 10 days post-inoculation into $1/10^{th}$ NB at room temperature with shaking at 85 rpm. Highest antibacterial activity of A115 was observed after 30 days of incubation (Figure 4) whereas F4 showed highest antibacterial activity after 50 days of incubation (Figure 5). Antibacterial activity of A115 and F4 strains decreased drastically at 40 and 60 days of incubations respectively (Figure 4 and 5).

Extraction of anti-MRSA compounds

It was found that the strain A115 produced a pink, cell-associated pigment. However, the role of pigment in antibacterial activity was not determined. The extraction methods including different resin treatments and organic solvent partitioning were investigated at the NCNPR for efficient recovery of anti-MRSA activity from supernatants and cell lysates. Ethyl acetate and methanol extractions of crud extracts of A115 supernatant showed IC_{50} of 4.42 and 4.17 µg/mL, respectively, against a MRSA strain. Preliminary LC-MS analysis of A115 supernatant failed to identify a UV-active compound with anti-MRSA activity. An investigation is ongoing to scale-up cultures in media that promote high anti-MRSA activity in order to obtain sufficient compound for biochemical structure elucidation.

It was observed that strain F4 produced a reddish pigment and its anti-MRSA activity is associated with a size fraction greater than 100kDa. The anti-MRSA activity is maintained even

after 10 min of boiling (Figure 3B). However, antimicrobial activity was not found from the F4 supernatant after filtration with 0.22 or even 0.45µm filter (Figure 3C). This finding demonstrated that the anti-MRSA compound(s) produced from F4 strain might be a high molecular weight compound(s) which might be (associated with) the reddish pigment. The extraction method including XAD-7 resin treatment revealed efficient extraction of active compound(s) of F4 supernatant (Figure 6) but subsequent HPLC analysis did not identify any active fraction.

Morphological and biochemical characteristics of *Actinobacteria* strains A115 and F4

On $1/10^{th}$ NA plates, strain A115 took 7-10 days to form visible colonies on a plate and the colony size gradually increased with increasing incubation times (up to a month). Highly filamentous colonies with massive aerial hyphae were observed after a month of incubation. Increasing the incubation time also increased the pink pigment production and the center of the colony had apparent aerial hyphae. In the case of strain F4, colonies typically appeared after 3-4 weeks of incubation on $1/10^{th}$ NA at room temperature. The colonies were initially white in color and completely grown into the agar, colony was collected by cutting the entire agar surrounding the colony. Increasing incubation time up to 3 months increased the production of brown or reddish color of pigment. Scanning electron microscopic observations demonstrated very different morphological features of two actinobaterial isolates (Figure 7 and 8). Biochemical and physiological characteristics of A115 and F4 were presented in Table 1. The fatty acid analysis of both strains revealed no significant match with any previously identified *Actinobacteria* species. The major fatty acid components of A115 were C15:0 iso, anteiso and C16:0 iso. For F4

strain, the major fatty acids were C15:0 iso, C16:1 iso and 10 methyl C17:0. Based on unique morphological, physiological and biochemical properties, these two isolates are both predicted to be novel *Actinobacteria* species. In order to improve the production of secondary metabolites by A115 and F4 strains in different laboratory conditions, several growth media and culture incubation conditions were tested (Table 2). It was established that the SYZ and $1/10^{th}$ NB media were the best for antibiotic production by A115 and F4, respectively.

Phylogenetic analysis

To determine the evolutionary relationships of the anti-MRSA isolate A115, a *16S rRNA gene sequence* based phylogenetic analysis was conducted using a total of 60 *Streptomyces* strains that included isolate A115 and 59 other *Streptomyces* strains sequences available in the GenBank of NCBI. The phylogenetic tree reconstructed from these near-complete (1,389 bp) 16S rRNA gene sequences (Figure 9) showed that isolate A115 clusters with members of the genus *Streptomyces*. The 16S rRNA gene sequence of isolate A115 is most closely related to that of *S. afghaniensis* strain 772 and *S. olindensis* DAUFPE 5622. A clear branching of isolate A115 from this species was strongly supported on the basis of 100% bootstrap values. BLASTn searching of the GenBank database using 1,389 bp 16S rRNA gene sequence revealed that isolate A115 is most closely related to strains belonging to the genus *Streptomyces* (84-95% similarity). The greatest % identity of the isolate A115 16S rRNA gene was with *S. afghaniensis* 772 and *S. olindensis* DAUFPE 5622, both which were observed to have 95% identity with their respective 16S rRNA gene sequences (Table 3). The low % identity of the isolate A115 16S rRNA gene with any other *Streptomyces* sp., below the 97% cutoff that is commonly used, suggested that this isolate is a novel species of *Streptomyces*. Because bacterial species cannot be defined solely on the basis of a 16S rRNA gene, a more robust phylogenetic analysis was

required to establish whether strain A115 was truly a representative of a novel *Streptomyces* species.

To provide a more refined phylogenetic placement of the anti-MRSA isolate A115, a multilocus sequence-based phylogeny was conducted that included 8,419 bp of concatenated nucleotide sequences from six housekeeping genes such as 16S rRNA, DNA gyrase subunit B (*gyrB*), RNA polymerase beta factor (*rpoB*), bacterial DNA recombination protein (*recA*), ATP synthase beta subunit (*atpD*) and tryptophan synthase beta subunit (*trpB*). MLSA clearly distinguished isolate A115 from the others and represented a distinct lineage. The multi-locus sequence analysis clearly segregated strains from individual species according to the established species delineation of *Streptomyces* genus (Figure 10), supported by 100% bootstrap value. Sequences of isolate A115 clustered separately from those of all previously described *Streptomyces species*. This multilocus phylogeny demonstrated that the anti-MRSA isolate A115 formed one independent lineage clearly separated from other 58 *Streptomyces* isolates used in this study (Figure 10). MLSA phylogenetic tree revealed that isolate A115 is closely related but independently branched from *S. afghaniensis* strain 772 and *S. olindensis* DAUFPE 5622. This finding is concordant with the 16S rRNA based phylogeny that demonstrated that isolate A115 is a separate clade from the other *Streptomyces* species described previously. Taken together, these findings support the hypothesis that isolate A115 is a novel *Streptomyces* species.

In addition, the evolutionary relationships of the anti-MRSA isolate F4 was determined by using *16S rRNA gene sequence.* Phylogenetic tree was constructed using a total of 97 *Nonomuraea* strains that included isolate F4 and 95 other *Nonomuraea* strains sequences available in the GenBank of NCBI. The phylogenetic tree reconstructed from these near-

complete (1,304 bp) 16S rRNA gene sequences (Figure 11) showed that isolate F4 clusters with members of the genus *Nonomuraea*. The 16S rRNA gene sequence of isolate F4 is most closely related to that of *N. antimicrobica*.

Average nucleotide identity (ANI)

Since average nucleotide identity (ANI) is a most reliable measurement of genomic relatedness between strains to determine their species demarcation (Kim et al. 2014), the genome sequence of anti-MRSA isolate A115 was compared against 39 strains of *Streptomyces*. All the strains that were compared against A115 genome showed ANI values less than 90% (Table 4). The genome of *S. afghaniensis* 772 showed highest similarity with A115 strain with ANI of 89.76% which is lower than ANI of 95% to be considered as member of the same species. This finding is consistent with the 16S rRNA gene based phylogenetic analysis which showed *S. afghaniensis* 772 as a closest neighbor to isolate A115. The A115 ANI of lower than 95% determined against a large number of *Streptomyces* species including its closest neighbor suggests that A115 isolate is a novel species of *Streptomyces*.

Prediction of secondary metabolite biosynthesis gene clusters in *Actinobacteria* strains A115 and F4

Secondary metabolite biosynthesis gene clusters for strains A115 and F4 were predicted using the secondary metabolite identification tool antiSMASH3.0 (Blin, Medema et al. 2013). Primary analysis of the A115 and F4 contig sequences revealed that A115 and F4 encode 69 and 66 secondary metabolite biosynthetic gene clusters respectively. However, using whole genome sequences of A115 and F4 suggested that these genomes encode 34 and 24 biosynthetic gene clusters respectively (Figure 12 and 13). This observation suggested the power of using whole

genome sequencing for identifying complete biosynthetic pathways for antibiotic production, some of which will not be identified otherwise.

5. Discussion

The emergence of multidrug-resistant pathogens has increased the demand for discovery of novel antibiotics (Bush 2011; Shlaes et al. 2004; Falkinham et al. 2009). New antibiotics are in high demand for the treatment of *Staphylococcus aureus* infections particularly due to the emergence of methicillin-resistant *S. aureus* (MRSA) in communities (**Hageman et al. 2006**; Lewis 2012). MRSA infections were initially restricted to hospitals, but are now widely present in the community (Lewis 2012).

The best possible source for new antibiotics with potentially novel mechanisms of action is within natural environments, particularly soils (Ling et al. 2015), which have the greatest diversity of microbial life. Soil is densely populated with microorganisms that produce small bioactive molecules, including antibiotics, anticancer compounds, immunosuppressive agents, insecticides, and others (**Handelsman et al. 1998;** Omura et al. 1992; Paradkar et al. 2003; Pettit et al. 2004). Over two-thirds of clinically-used antibiotics are natural products or semi-synthetic derivatives (Fair et al. 2014). Most of these have been derived from cultured microorganisms, which represent <1% of the total soil community (Torsvik, Goksøyr et al. 1990; Amann et al. 1995). Because soil is estimated to harbor $>10^5$ species per gram (Hartmann et al. 2006), there exists extensive undiscovered functional diversity (Lewis et al. 2010). However, although there has been a wealth of antibiotics discovered from cultured soil microbes (Thiele-Bruhn 2003), the past several decades have experienced diminishing success rates for antibiotic discovery using a culture-based approach. This is due to the very high rate of antibiotic re-discovery (>99%) when

screening cultured bacteria grown under “normal” laboratory conditions, i.e. high nutrient levels with short incubation times. Novel culturing techniques can help to access a greater diversity of antibiotics produced by previously uncultured microorganisms.

In this study, a low-nutrient medium supplemented with a soil extract combined with very long-term incubation approaches were used to avoid the re-isolation of previously identified burden of background for screening of common bacteria. Results of present study suggesting that the addition of soil extract to medium and longer incubation time are helpful for the isolation of bacteria from soils. Phylogenetic analysis revealed the presence of diverse bacterial phyla in soil and the overall bacterial diversity showed significant variability among samples. In this study, only the pure culture isolates were ribotyped which might not represent the true bacterial diversity that were present in the soil samples since majority of soil bacteria are recalcitrant to cultivate in laboratory conditions. Out of 548 soil isolates two of them have potential to inhibit the growth of clinical MRSA strains. These two bacteria, isolates A115 and F4, are affiliated with the phylum *Actinobacteria* and a phylogenetic analysis based on *16S rRNA gene sequence* analysis using *Streptomyces* strains sequences available in the GenBank showed that isolate A115 clusters with members of the genus *Streptomyces*. The greatest % identity of the isolate A115 16S rRNA gene was with *S. afghaniensis* 772 and *S. olindensis* DAUFPE 5622, both of which were observed to have 95% identity with their respective 16S rRNA gene sequences. Since the % sequence similarity of 16S rRNA gene sequence is less than 97% which has been widely used as a threshold for bacterial species delineation, the isolate A115 considered as a novel species. More rigorous phylogenetic analysis with six housekeeping genes using MLSA revealed that the isolate A115 is closely related but independently branched from *S. afghaniensis* strain 772 and *S. olindensis* DAUFPE 5622. Furthermore, the comparative study based on ANI

values of whole genomes indicating lower than 95% identity that can be considered A115 as member of the same species. Therefore, the isolate A115 can be considered as a novel *Streptomyces* species. The identification of *Streptomyces* isolates has been extremely important historically for antibacterial screening, as this genus is proven to be the prolific producers of novel antibiotics (Watve et al. 2001) with approximately 75% of commercially useful antibiotics being derived from them (Guo et al. 2015).

The genus *Nonomuraea* belongs to rare *Actinobacteria* that promise a raise in the prospect of discovering novel compounds with potential antimicrobial activities (Tiwari et al. 2012). Here in this study, strain F4 was isolated from forest soil which belonged to the genus *Nonomuraea,* had strong antibacterial activity against clinical MRSA strain. Whole genome sequencing of F4 strain revealed high G+C% of 70.4 and relatively larger genome of 10.3 Mbp which is similar to three other available complete genomes of *Nonomuraea* species such as *N. coxensis* (G+C% 72; 9.0Mb), *N. candida* (G+C% 72.1; 11.01Mb) and *N. kuesteri* (G+C% 70.5; 13.36Mb). Phylogenetic analysis based on 16S rRNA gene sequence revealed *N. antimicrobica* YIM 61105 as the closest neighbor of *Nonomuraea* sp. strain F4. In the phylogenetic tree, 16S rRNA sequence of F4 strain produced a monophyletic branch with *N. antimicrobica* with bootstrap value of 93%, however, these two isolates showed significant differences in their morphological, physiological and biochemical characteristics. Because of few available whole genomes sequences of *Nonomuraea* spp. in public database, we were not able to calculate ANI values of F4 strain with other *Nonomuraea* spp. to determine the genetic relatedness between strains. ANI is one of the most robust measurements of genomic relatedness between strains and has potential to use as an alternative of DNA-DNA hybridization (DDH) technique for species delineation (Kim et al. 2014). Therefore, we cannot confirm whether strain F4 should be

belonged to the species *N. antimicrobica* only based on 16S rRNA gene specific phylogenetic tree. Although 16S rRNA gene is the most widely used phylogenetic marker in microbial ecology, however, the presence of multiple copies of this gene in a single bacterium can influence the phylogenetic resolution and operational taxonomic unit estimation at the species level or below (Case et al. 2007). Since 16S rRNA gene is evolutionarily conserved, using this sequence for delineating species designation using phylogenetic analysis is difficult. Therefore, alternative molecular marker such as MLSA studies using several housekeeping genes should be used to classify bacterial isolates to the species level.

Several attempts have been taken for biochemically characterize antibacterial compound(s) produced by this strain was unsuccessful; the reason behind this may be due to the large size of the active compound and failure to use appropriate extraction procedures for compound separation. Thus, future research to develop an efficient and sensitive analytic system for active compound analysis from this strain will be of special interest.

Taken together, our findings indicated that novel culturing can be applied to identify novel species of *Actinobacteria* from soil and some of which can be used as therapeutics to prevent infections caused by MRSA.

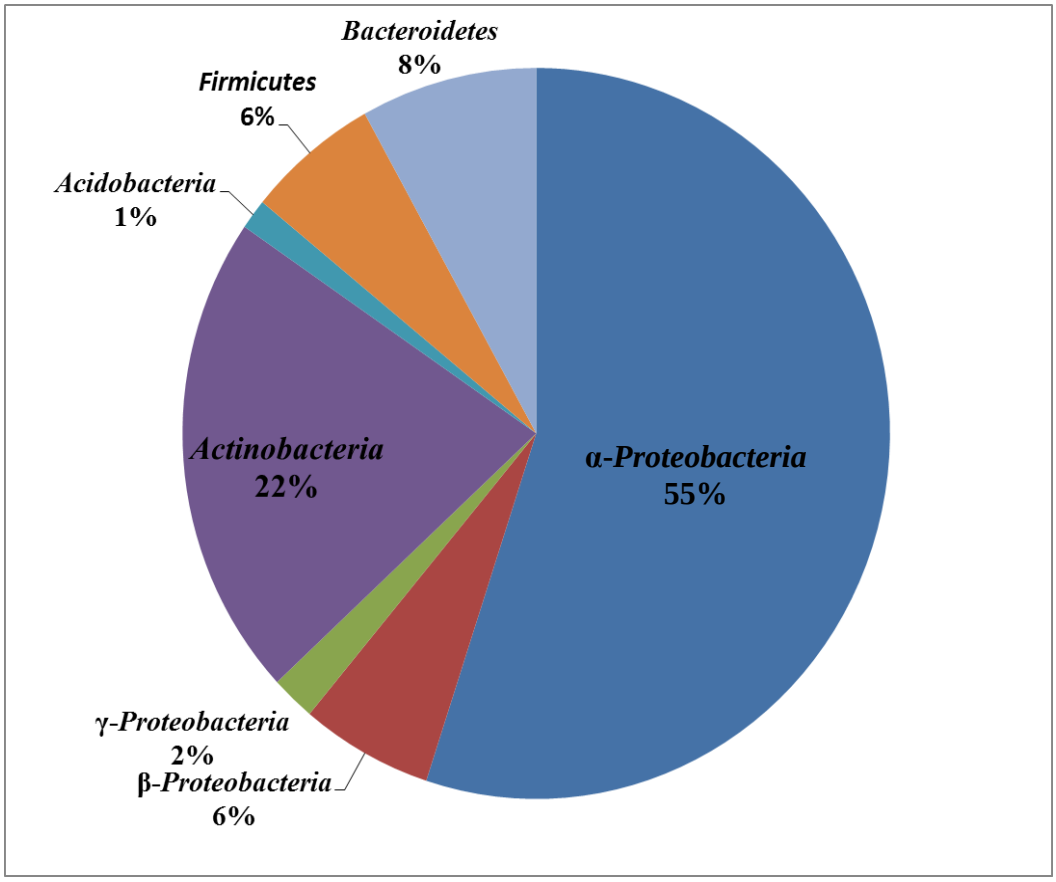

Figure 1A. Bacterial Phyla representation of cultured isolates from the sample of Black belt soil (Auburn University Arboretum, from soil removed during the construction of the Auburn University-Montgomery campus).

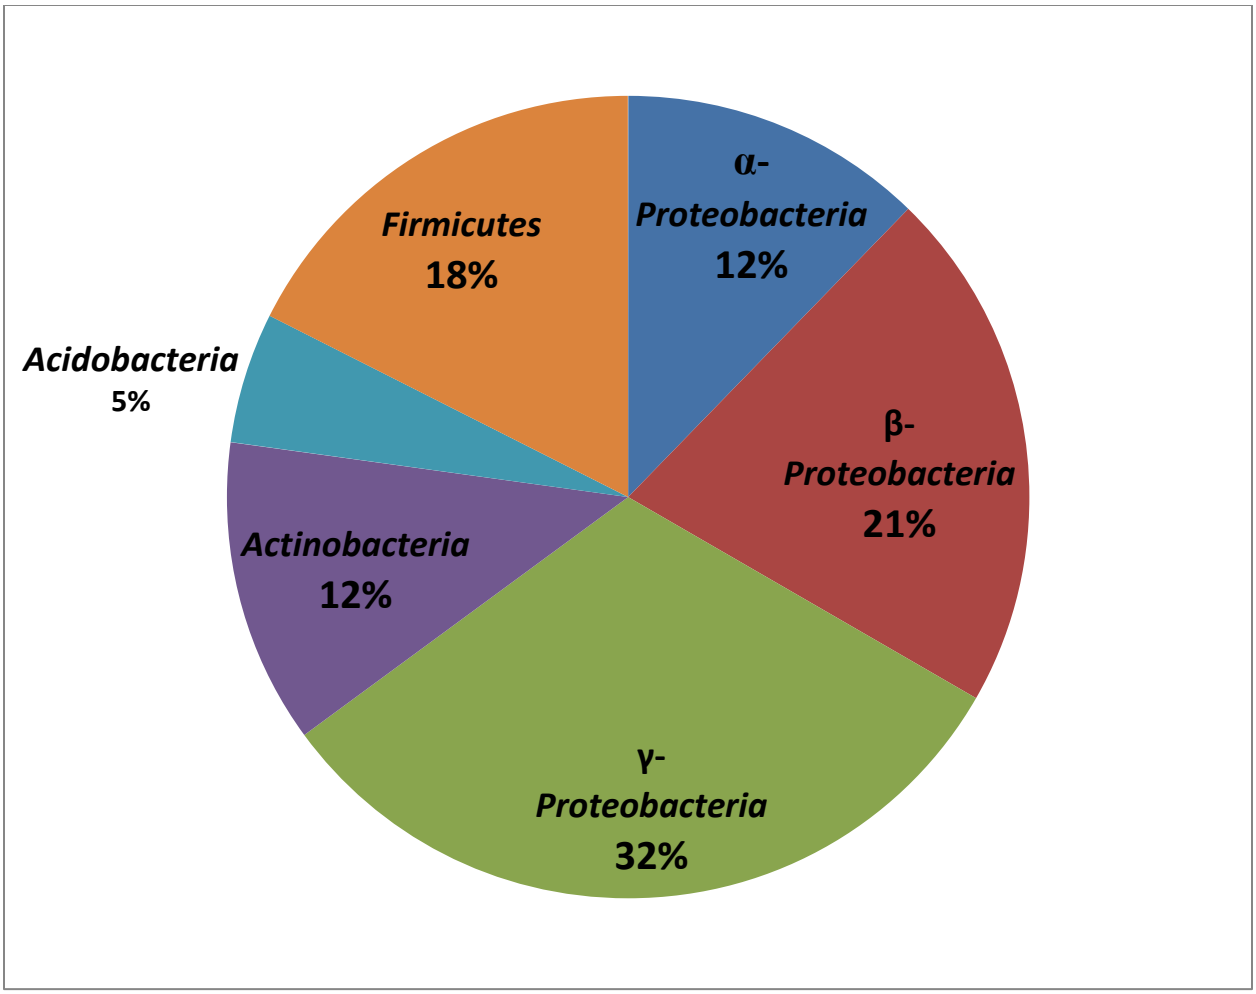

Figure 1B. Bacterial Phyla representation of cultured isolates from the sample from the Cullars Rotation agricultural soil (Auburn, AL).

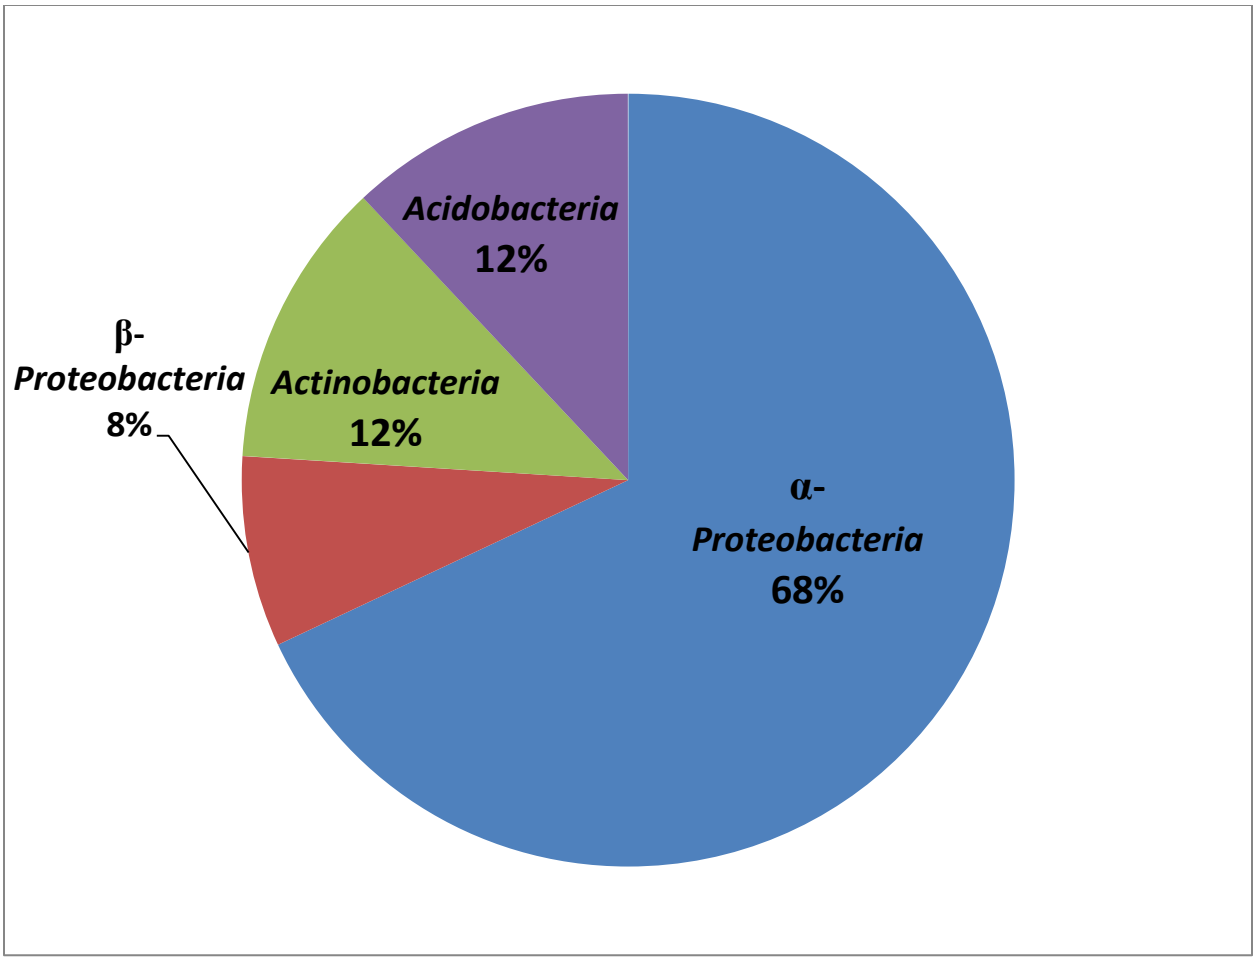

Figure 1C. Bacterial Phyla representation of cultured isolates from a sample from a forest soil adjacent to a long-leaf pine tree (Auburn, AL).

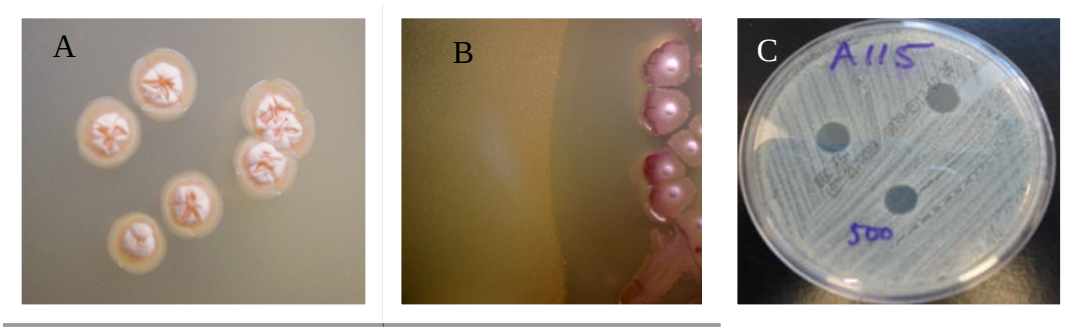

Figure 2. Culture A115 (Phylum *Actinobacteria*, genus *Streptomyces*) produces a pink pigment that is cell-associated (Panel A) and excretes a potent anti-MRSA activity (Panel B) demonstrated here by a soft agar overlay with a clinical MRSA strain 30. The anti-MRSA activity is present in cell-free bacterial supernatants when grown in 1/10th strength Nutrient Broth (Panel C).

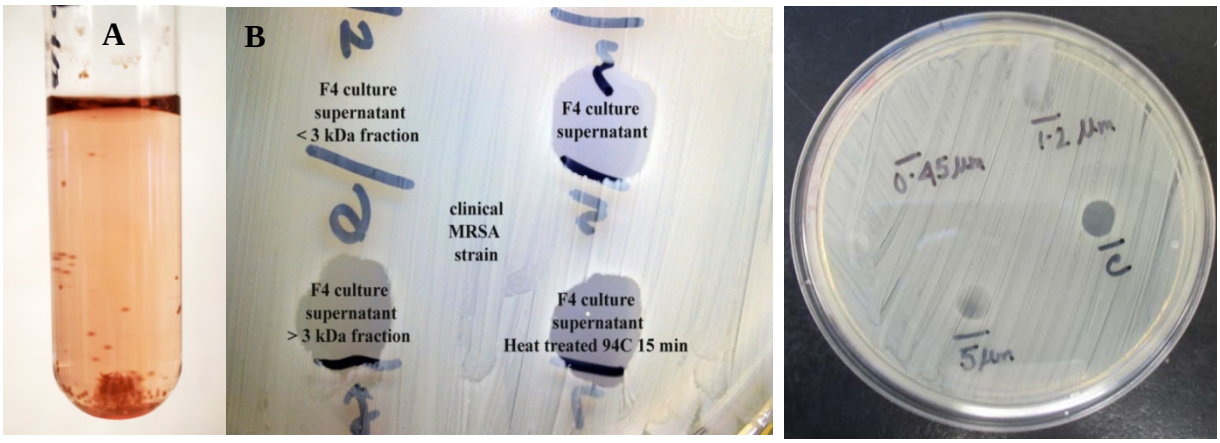

Figure 3. Culture F4 (Phylum *Actinobacteria*, genus *Nonomuraea*) produces a high molecular weight, reddish pigment (panel A) and this same fraction has a heat stable (Panel B), anti-MRSA activity (Panel C) as shown on a lawn of a clinical MRSA strain 30.

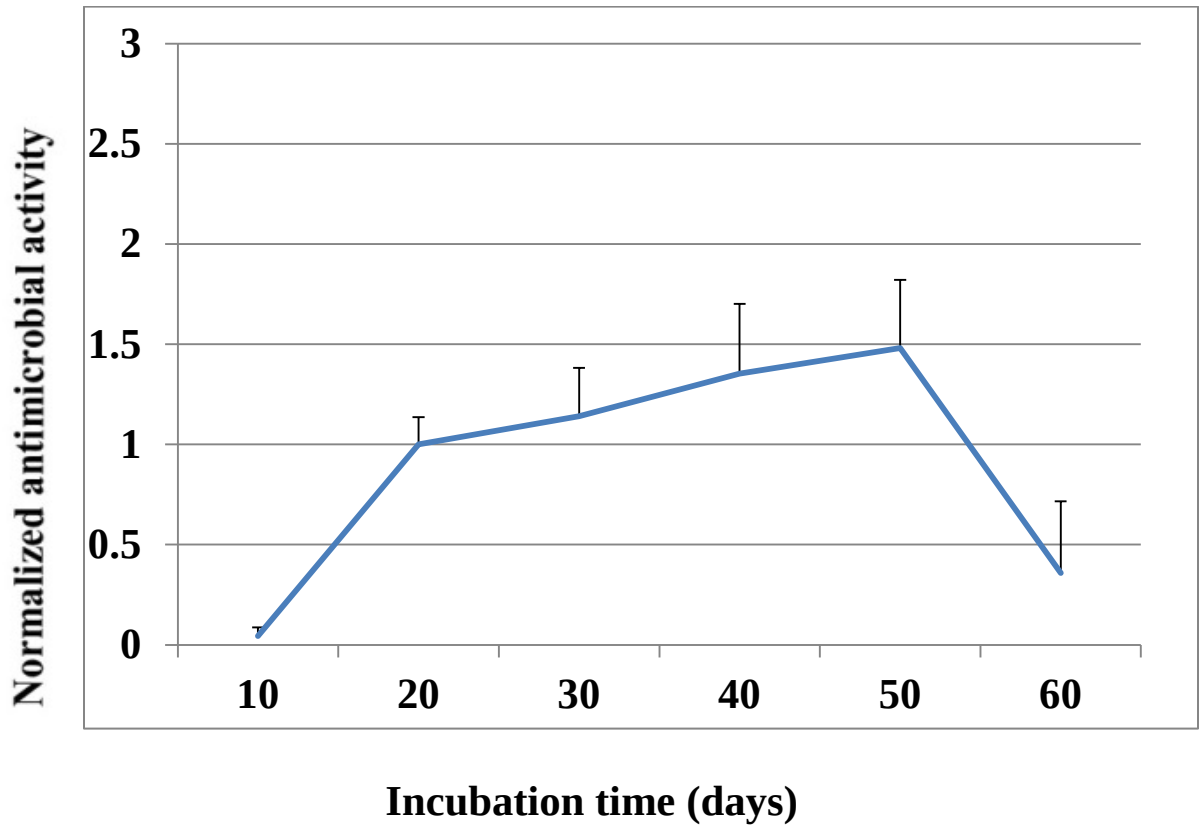

Figure 4. Normalized antibacterial activity of A115 supernatant against MRSA strain 30. A115 strain was grown for 2 months in 1/10th NB at room temperature and supernatant was tested from different time points of incubation.

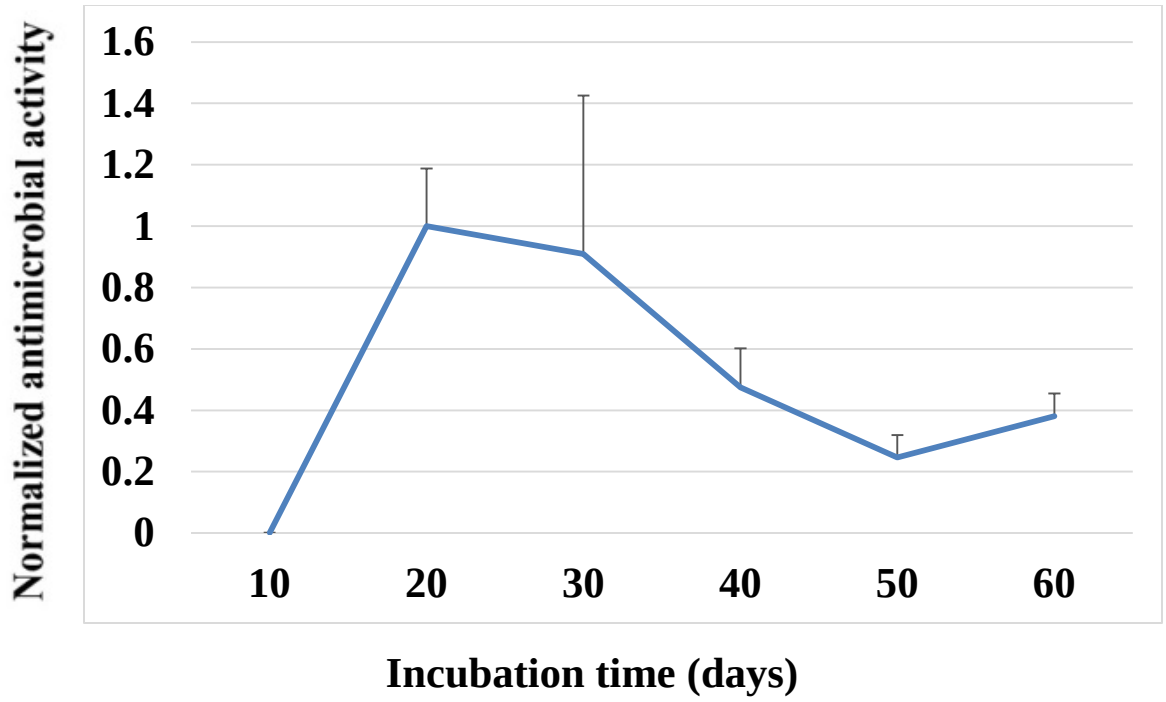

Figure 5. Normalized antibacterial activity of F4 supernatant against MRSA strain 30. F4 strain was grown for 2 months in 1/10th NB at room temperature and supernatant was tested from different time points of incubation.

Figure 6. Extraction of anti-MRSA compound(s) of F4 supernatant by XAD-7 resin treatment. Fractions 2 to 6 labeled as EL-2 to EL-6 contained active compound that was demonstrated by drop assay.

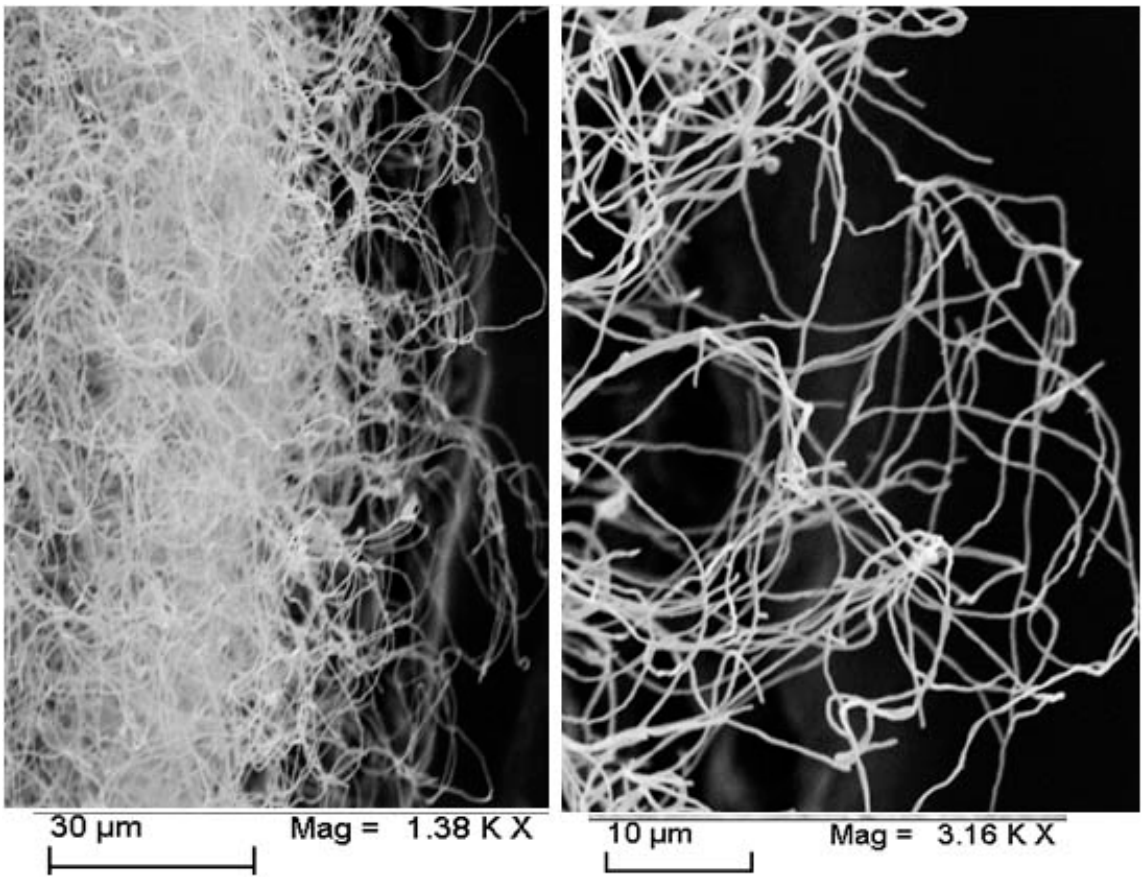

Figure 7. Scanning electron micrograph of *Streptomyces alburnustigris* strain A115 showing mycelial structures after 3 weeks of incubation at room temperature in 1/10th NB.

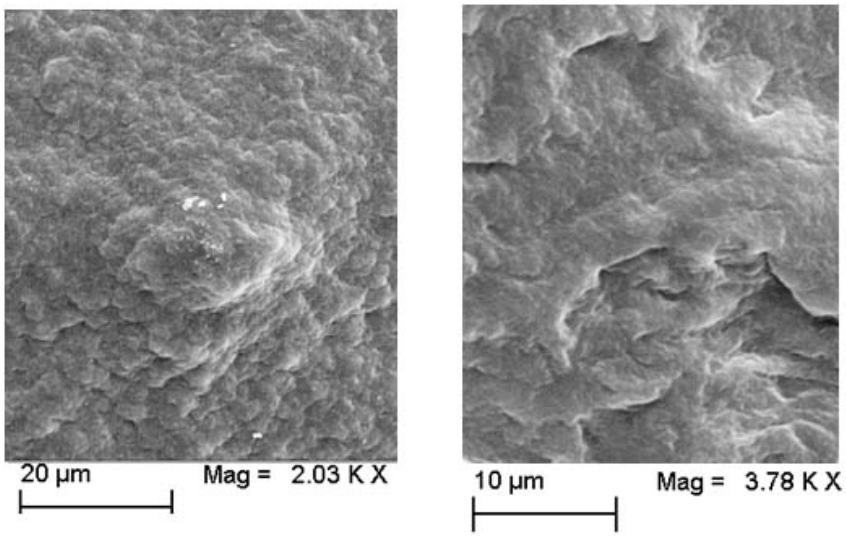

Figure 8. Scanning electron micrograph of *Nonomuraea* sp. strain F4 showing compact structures of cells after 3 weeks of incubation at room temperature on 1/10th NA.

Figure 9. Phylogenetic tree reconstructed based on 16S rRNA gene sequences showing the evolutionary relationship among anti-MRSA isolate A115 and members of the genus *Streptomyces*. The tree was inferred using the maximum likelihood method. The 16S rRNA sequences of *Mycobacterium tuberculosis* strain H37Rv was used as an outgroup. Numbers at each branch nodes indicate bootstrap percentages based on the maximum likelihood method (1000 replicates) that was calculated using MEGA 6.0 software (Tamura et al. 2011). Bar indicates 5 substitutions per 100 positions.

Figure 10. Phylogenetic tree of concatenated sequences of genes 16S rRNA, *atpD*, *gyrB*, *rpoB*, *recA*, and *trpB* of species of the genus *Streptomyces*. The tree was inferred using the maximum likelihood method. *Mycobacterium tuberculosis* strain H37Rv was used as an outgroup to root the tree. Bar indicates proportion of nucleotide substitutions. Values at the nodes denote bootstrap support (in percentage) obtained based on 1000 replicates.

Chapter 3

Isolation and characterization of anti-MRSA active compounds from *Bacillus* spp. strains and their potential use as a skin probiotic.

1. Abstract

Skin and soft tissues are the most common sites of *Staphylococcus aureus* infection and inhibition of *S. aureus* skin colonization can potentially prevent life-threatening bacteremia. The emergence of methicillin-resistant *S. aureus* (MRSA) strains has increased the demand for new strategies to combat and prevent infection. We screened a library of bacterial isolates to identify novel chemical compounds for MRSA control. We identified five *Bacillus* strains that expressed metabolites with anti-MRSA activity and used LC-MS to characterize antibacterial compounds expressed by these strains. The *B. amyloliquefaciens* strain AP183 was found to produce a novel macrodiolide compound described herein as bacillusin A with potent anti-MRSA activity of a minimum inhibitory concentration of 0.6 µg/mL. Because Bacillusin A has a short half-life after extraction, and we hypothesized that it may not persist within living tissue and would therefore be suitable for *in vivo* application. AP183 was tested *in vivo* as a skin probiotic to prevent MRSA infection using a mouse model. Mice were simultaneously challenged with bioluminescent *S. aureus* strain Xen29 with and without AP183 spores in two separate wounds. In additional experiments, we tested the effects of AP183 spores with and without accompanying secondary metabolites. After challenge, skin wound healing was monitored for one week and *S. aureus* growth was assessed by bioluminescent imaging. After one week, mice were sacrificed and wounds were homogenized and plated to determine culturable bacterial counts and confirmed by

conducting a culture-independent skin microbiome analysis. Our *in vivo* studies showed that co-administration of secondary metabolites and AP183 spores resulted in a significant reduction in the number of *S. aureus* colonization compared to a negative control. Molecular analysis has also shown a significant reduction in *S. aureus* relative abundance when AP183 was applied while the relative abundance of other bacterial taxa increased in the skin microbiome as a result of probiotic administration. In future work, we will determine the *in vivo* efficacy and safety for the application of strain AP183 and its active metabolites.

2. Introduction

The indiscriminate use of antibiotics has led to an increase bacterial resistance especially for Gram-positive pathogens, *Staphylococcus aureus*, *Enterococcus* and coagulase-negative *Staphylococcus* that pose serious problem in treating infections caused by these pathogens (Tarai et al. 2013). *S. aureus* is among the most common causative agents involved in skin infections in the United States (Edelsberg et al. 2009). An untreated minor skin infection caused by *S. aureus* can spread quickly and progress into more serious condition including distal abscesses of the kidneys and spleen, sepsis and endocarditis (DeLeo et al. 2009). Since skin and soft tissues are the most common sites of *S. aureus* infection, inhibition of *S. aureus* skin colonization can potentially prevent life-threatening bacteremia. The emergence of (MRSA) strains and the life-threatening diseases accompanying MRSA strains has subsequently increased the demand for new antibiotics (DeLeo et al. 2009; Wright 2015).

Members of the genus *Bacillus* are well known to be a prolific source of bioactive natural products (Hamdache et al. 2011; Stein 2005). The *Bacillus* genus is comprised of Gram-positive aerobic or facultative anaerobic, spore forming, rod shaped bacteria that are common in soil. *Bacillus* spp. that have been screened for antimicrobial activities over the past few decades

(Mannanov et al. 2001; Chen et al. 2009). Strains within the *B. subtilis* group, which includes the species *B. amyloliquefaciens,* have been used as biocontrol agents against plant and animal pathogens in agriculture and aquaculture (Ongena et al. 2008; Cook et al. 1995; Ran et al. 2012; Mohammad et al. under review). Plant growth-promoting rhizobacteria (PGPR) the bacteria can promote plant growth directly by helping plants acquire nutrition from soil, or indirectly by controlling phytopathogens to prevent plant diseases (Kloepper et al. 1980). PGPR result in significant enhancement of plant growth and increases yields of agronomically important crops. In addition to plant growth promotion and disease control, several publications suggest that *B. amyloliquefaciens* can also improve well-being of animals through use asa potential probiotic and/or as a curative agent (Islam et al. 2011; Ahmed et al. 2014; González-Ortiz et al. 2013). The majority of antibiotics produced by *Bacillus* spp. are low molecular weight polypeptides that are synthesized by ribosomal or non-ribosomal mechanisms. Many *Bacillus* spp. are known to produce polyketides with antibiotic activities such as macrolactins, difficidins, and oxidifficidins, as well as lipopeptides such as surfactins, iturins, and fengycins (Hamdache et al. 2011; Stein 2005; Sumi et al. 2014). *B. subtilis* strains are the prominent producers of surfactin antibiotics, which exhibit antibacterial and antiviral activity (Wang et al. 2008; Ongena et al. 2007). Iturins produced by various strains of *B. subtilis* are amphiphilic compounds with a peptide ring of seven amino acid residues, including an invariable D-Tyr2 residue (Maget-Dana et al. 1994). The members of iturins family exhibit potent antifungal activity. Iturins A showed strong antimicrobial activity against fungal pathogens *Phythium ultimum*, *Rhizoctonia solani*, *Fusarium oxysporum*, *Sclerotinia sclerotiorum* and *Macrophomina phaseolina* (Li et al. 2014). In addition to iturins, *Bacillus* species produce several other antibiotics that include lantibiotics (Stein et al.

2002), kanosamine (Milner et al. 1996), zwittermycin A (Silo-Suh et al. 1998), bacillomycin (Volpon et al. 1999), plipastatins (Volpon et al. 2000), and bacillusin A (Ravu et al. 2015).

Bacillusin A is a recently discovered macrocyclic polyene antibiotic from *B. amyloliquefaciens* strain AP183 which showed potent antibacterial activities against MRSA and vancomycin-resistant *Enterococcus faecium* with minimum inhibitory concentrations in a range of 0.6 to 1.2 µg/mL (Ravu et al. 2015). Bacillusin A has a short half-life after extraction, which might prove pharmaceutically beneficial for infected wounds where rapid elimination of antibiotic residues can be an advantage.

Following determination of bacillusin A as a potent antibacterial agent capable of inhibiting MRSA growth, genome sequencing of its producer *B. amyloliquefaciens* strain AP183 was performed to determine the gene(s) responsible for the synthesis of bacillusin A. From an analysis of the AP183 genome, the trans-AT polyketide synthases (PKS) pathways were predicted to be responsible for synthesis of bacillusin A (Nasrin et al. 2015).

Strains of *B. amyloliquefaciens* have been used previously as probiotics in animals and plants and are not associated with disease (Ahmed et al 2014; González-Ortiz et al. 2013). The beneficial effects of probiotics include antagonism to pathogens, enhancement of immune response and restoration of body's normal flora (Sun et al. 2010; Casula et al. 2002). There are many strains of *B. amyloliquefaciens* that have already been developed for use with crops, livestock, or products for human consumption (Krober et al. 2014; Lee et al. 2012); however,the use of*B. amyloliquefaciens* strains as a skin probiotic to inhibit cutaneous wound colonization of MRSA has not been reported previously. Since *Bacillus* spores are highly stable and large-scale production of spores is well described (Monteiro et al. 2014), it may be possible to incorporate *Bacillus* spores into different formulations for topical application (e.g., Band-aid, lotions). The

practical considerations for scale-up and eventual application(s) are highly favorable for use in preventing or treating skin infections caused by MRSA. Thus, we developed we developed a novel and clinically applicable method for combating dermal MRSA infections by utilizing spores and metabolites of AP183.

3. Materials and methods

Microorganisms and growth conditions

In this study, a collection of 177 *Bacillus* spp. strains were screened *in vitro* for antimicrobial activities against number of bacterial and fungal pathogens (Table 1). Out of 177 *Bacillus* spp. strains, 160 strains were PGPR *Bacillus* spp. strains which were provided by the laboratory of Dr. Joseph Kloepper (Department of Entomology and Plant Pathology, Auburn University). An additional 17 *Bacillus* spp. strains were isolated from catfish gut (Ran et al. 2012). The tester bacteria methicillin-resistant *Staphylococcus aureus* strain number EAMC30 was a clinical MRSA strain obtained from East Alabama Medical Center, Opelika, AL, provided by Dr. James Barbaree (Department of Biological Sciences, Auburn University). Bioluminescent *S. aureus* strain Xen29 was purchased from PerkinELmer (USA). In addition, methicillin-susceptible *Staphylococcus aureus* ATCC 29213, methicillin-resistant *Staphylococcus aureus* ATCC 29213, *Enterococcus faecalis* ATCC 51299, *Enterococcus faecalis* ATCC 29212, *Enterococcus faecium* ATCC 700221, and the yeast *Candida albicans* ATCC 90028 were purchased from the American Type Culture Collection (Manassas, VA). Both *Bacillus* spp. and *S. aureus* strains were routinely grown and maintained in Tryptic Soy Broth (TSB) and /or in TSB media supplemented with 15 g/L agar (TSA) at 30°C and 37°C, respectively. All bacterial isolates were cryopreserved at -80°C.

Screening of *Bacillus* spp. strains with antimicrobial activities

Antibiosis assays were carried out with double-layer soft agar method with minor modifications (Jack et al. 1996). Briefly, each of the *Bacillus* isolates were grown in TSB media on a rotatory shaker at 200 rpm for 24 hours at 30°C. Prior to the inoculation of bacilli, a sterile cork borer of 10 mm diameter was used to bore wells in those water agar plates and wells were filled with ~1.0 mL of TSA. 10 µL of each *Bacillus* culture was then spotted onto duplicate plates of water agar and incubated for 48 hours at 30°C. After 48 hours of incubation, soft agar (0.7% w/v agar) prepared with TSB was melted, cooled, and seeded with a freshly prepared inoculum of log-phase MRSA strain 30 to achieve the absorbance at 600 nm (OD_{600}) of 0.5. The bacterial cell suspension in soft agar was immediately poured over the water agar plates and incubated for 24 hours at 37°C. After incubation, the zones of clearing in the growth of MRSA strain 30 were recorded (in mm) as evidence of growth inhibition by corresponding *Bacillus* spp. strains.

To verify antimicrobial activity, the entire collection of *Bacillus* strains was further screened by drop assay. In this assay *Bacillus* strains were grown in TSB on a rotatory shaker at 200 rpm for 48 hours at 30°C. Cells were harvested by centrifugation at 8000 rpm for 10 min. Supernatants were filtered and frozen for further analysis. A broth culture of actively growing MRSA strain 30 was adjusted to OD_{600} of 0.5 and evenly swabbed onto TSA plates. Next 10 µL of cell-free supernatant derived from *Bacillus* culture was added onto the MRSA strain 30 culture. Zones of inhibition were measured after 24 hours of incubation at 37°C. An aliquot of supernatants from different *Bacillus* strains were also shipped to the National Center for Natural Products Research (NCNPR) at the University of Mississippi for screening against a larger collection of bacterial and fungal pathogens.

Phylogenetic analysis of *Bacillus* spp. strains producing anti-MRSA compound

Five *Bacillus* isolates that include AP143, AP183, AP191, AP218 and AB01 with consistently strong antimicrobial activities in three independent *in vitro* antibiosis assays were selected for phylogenetic analysis using 16S rRNA gene-specific sequences. For colony PCR, universal bacterial primers 27F and 1492R, which generated approximately 1.5kb products, were used. PCR reactions were performed in 50µL reaction volumes which contained 25.0 µL of 2x EconoTaq plus Green DNA Polymerase (Lucigen Co. WI), 0.2µM of each primer and sterile distilled water for adjusting to 50 µL. Amplification of 16S rRNA gene was carried out under the following conditions: denaturation at 94°C for 2 min, followed by 35 cycles of 94°C for 30 s, 55°C for 30 s, 72°C for 2.0 min, and final extension at 72°C for 10 min. Amplified PCR products of *Bacillus* isolates were analyzed by electrophoresis with 0.7% agarose gel run at 200V for one hour. After electrophoresis, the gel was stained by ethidium bromide and then visualized and photographed under UV transilluminator using Gel Doc XR system (Biorad USA). The PCR products were purified by E.Z.N.A cycle pure kit (Omega bio-tak USA) according to the manufacturer's instructions and purified PCR products were then sequenced in both directions using primers 27F and 1492R (Lucigen Corp, Middleton, WI USA). The sequences were trimmed for quality using ChromasPro (Technelysium, Australia). Trimmed sequences were assembled and compared against sequences available in the National Center for Biotechnology Information (NCBI data base), GenBank using the BLASTn algorithm.

Preliminary LC-MS analysis

Supernatants from five anti-MRSA compound-producing bacilli were analyzed by LC-MS method at the National Center for Natural Product Research (NCNPR, Oxford, MS) according to the standard protocol established by the NCNPR (Ravu et al. 2015). Initial LC-MS

data revealed the presence of a potential novel compound in the supernatant derived *Bacillus* strain AP183.

Purification of active secondary metabolites from strain AP183

To purify anti-MRSA compounds from strain AP183, preliminary fractionation, isolation of fractions, and *in vitro* antimicrobial activity of the purified compound were determined as described by Ravu et al. 2015. Large-scale cultures of AP183 (≥1L) were grown in TSB for 48 hours at 30°C. Supernatant was filtered and shipped to the NCNPR for biochemical analyses, including LC/MS (liquid chromatography/mass spectrometry) and NMR (nuclear magnetic resonance) for biochemical structural elucidation.

Isolation of genomic DNA from strain AP183

To determine the whole genome sequence of *B. amyloliquefaciens* subsp. *plantarum* strain AP183, genomic DNA was extracted according to the methods described previously (Wilson 2001). The DNA concentration was measured by Qubit 2.0 fluorometer (Life technologies, USA) following the manufacturer's instructions.

Phylogenetic analysis of strain AP183

The *gyrB* gene from strain AP183 was PCR amplified and sequenced using *Bacillus* spp. specific universal primer sets UP-1 and UP-2r according to the methods described previously. The *gyrB* sequence-based phylogenetic tree was inferred with MEGA5.05 (Tamura, Peterson et al. 2011) using the Maximum Likelihood (ML) method (Felsenstein 1981) with 1000 iterations for bootstrap support.

Whole genome sequencing, assembly, and annotation

Next-generation sequencing of *Bacillus* strain AP183 was performed using the Illumina MiSeq sequencing platform. An indexed Illumina library was prepared using Nextera DNA

Sample Prep Kit (Epicentre, Madison, WI) and sequences were generated using an Illumina MiSeq with a 2 × 250 paired end sequencing kit. Sequence reads were trimmed for quality and assembled *de novo* using the CLC Genomics Workbench (CLCBio, Cambridge, MA). Gene prediction and annotation were performed using GeneMark (Lukashin and Borodovsky 1998) and RAST annotation server (Aziz, Bartels et al. 2008), respectively. The identity of individual ORFs from secondary metabolite biosynthesis gene clusters was confirmed by BLASTx against the GenBank database. The whole genome shotgun of AP183 was deposited at DDBJ/EMBL/GenBank under the accession no. JXAM00000000.

Prediction of secondary metabolite biosynthesis gene clusters in *Bacillus* strainAP183

Secondary metabolite biosynthesis gene clusters for strain AP183 were predicted using the secondary metabolite identification tool antiSMASH2.0 (Blin, Medema et al. 2013). Gene prediction and annotation were carried out by GeneMark (Lukashin and Borodovsky 1998) and BLASTx (NCBI), respectively.

Antibiotic resistance profile

The susceptibility of AP183 to broad range of antibiotics was determined by Kirby-Bauer disc diffusion method, outlined by National Committee for Clinical Laboratory Standards (CLSI 2012). A log-phase culture of AP183, diluted to a concentration of approximately 1×10^8 CFU/mL, was seeded onto a Mueller-Hinton agar plate. Antibiotic-impregnated discs (BD Biosciences) were placed onto the seeded plates with three replicates. The zone of inhibition was measured and recorded after 18 hours of incubation at 30°C.

Preparation of *Bacillus* spore formulation for mouse challenge

Five Bacillus species including AP143, AP183, AP191, AP218 and AB01were evaluated as a topical probiotic to inhibit the colonization of S. aureus on mouse skin wounds. Bacillus

spores were prepared according to the method described by Ran et al. (Ran et al. 2012). The concentration of the spore suspension was determined by serially diluting the spore suspension in sterile water and plating them in TSA plates for overnight incubation at 30°C. Spores were preserved at 4°C and the final concentration of the spore suspension for challenge studies were adjusted to 1.0×10^8 CFU/mL by diluting with 30% glycerol.

Preparation of *Bacillus* spores and metabolites formulation for mouse challenge

For this *in vivo* cutaneous infection model, a combination of AP183 spores and metabolites were used. For preparing the spores and metabolites formulation, a colony of strain AP183 was inoculated into a 20 mL culture tube containing 5.0 mL of TSB and incubated on a rotatory shaker at 200 rpm at 30°C for five days. Before mouse challenge studies, an aliquot of cell free supernatant was tested for anti-MRSA activity *in vitro* and the presence of spores were confirmed by spore staining. AP183 culture was dispensed into 1.0 mL aliquots containing 30% glycerol.

Preparation of *S. aureus* strain Xen29 inoculum for *in vivo* cutaneous wound challenge

S. aureus Xen29 used for *in vivo* cutaneous wound challenge studies was derived from the parental strain of *S. aureus* 12600 and possesses a stable copy of the *luxABCDE* operon at a single integration site on the chromosome. For mouse challenge studies, Xen 29 was grown overnight in Brain Heart Infusion (BHI) broth containing 50 µg/mL kanamycin with shaking at 225 rpm at 37°C. The overnight culture was then washed twice and diluted 1:100 into 1× sterile PBS with 10 % glycerol to achieve absorbance at 600 nm (OD_{600}) of 0.4 which are equivalent to 1.4×10^8 CFU/mL. For creating each wound, 10 µL of injection volume was used which contained ~1.0×10^6 CFU/mL of Xen29 cells.

Mice challenge studies

Experimental protocols were reviewed, approved and performed under regulatory supervision of Auburn University's Institutional Biosafety Committee (IBC) and Institutional Animal Care and Use Committee (IACUC). For *in vivo* challenge studies, female C57BL/65 mice of 6 to 8 weeks old were purchased from Jackson Laboratories (Bar Harbor, ME) and housed 3 to 5 animals per cage. These mice were fed standard alfalfa free rodent diet and distilled water.

In the first challenge, spores of five *Bacillus* spp. (strains AP143, AP191, AP183, AP218 and AB01) were selected for evaluation of their ability to inhibit colonization of *S. aureus* Xen29 in mouse cutaneous wound model. To induce skin infections, the mice were first anesthetized with isoflurane (2% (vol/vol)/2 liters O_2) (Panizzi et al. 2011) and the hair on the back of mice were shaved (electric clipper) and depilated (Veet; Reckitt Benckiser, Germany). Each mouse in the treatment group was simultaneously challenged with bioluminescent *S. aureus* strain Xen29 in two independent cutaneous wounds on each mouse back. The suspension of spores and/or Xen29 was injected subcutaneously in to 3 mice per treatment group. The concentrations of Xen29 and *Bacillus* spp. spores per wound were in the range of 1.0×10^7 and 1.0×10^8 CFU, respectively. Four to six hours of post challenge, mice were images for bioluminescence using IVIS Lumina XRms (Parkin Elmer) imaging system for monitoring the progress of Xen29 establishment in infection sites. The progression of skin abscess lesions was monitored daily for one week after challenge by Bioluminescent Imaging (BLI).

Three different formulations were evaluated in this *in vitro* model: a) spores, b) secondary metabolites and, c) combination of spores and metabolites of AP183. Bioluminescent *S. aureus* strain Xen29 was injected subcutaneously in mouse wound model (n=10 mice per treatment). After challenge, skin wound healing was monitored for one week and mice in each

treatment group were assessed for *S. aureus* growth by BLI flux (rate of photon per second, p/s) analysis.

Determination of staphylococcal survival in mouse wound

Mice were euthanized by induction of anesthesia with isofluran (2% (vol/vol)/2 liters O_2) followed by cervical dislocation. Then wounds including few millimeters of surrounding skin were excised with half of the excised wounds homogenized in PBS prior to serial dilution and spread plating. Plates were incubated for 18 hours at 37°C followed by bioluminescent imaging and counting of staphylococcal colonies present in each treatment group. The other half of the wound was prepared for histological analysis by Gram stain and H&E.

Microbial diversity analysis of the mouse skin

To assess the wound site-associated microbiota, genomic DNA was extracted from mouse wound tissue homogenates of each treatment group using genomic DNA isolation kit (Ultraclean microbial DNA isolation kit, MO BIO). Genomic DNA was extracted according to the manufacturer instructions and the extracted genomic DNAs were used as templates for PCR amplification of 16S rRNA genes with bar-coded “universal Bacteria” primer sets. Pooled amplicons were sequenced using paired-end reads on an Illumina MiSeq and several thousand 16S rRNA sequences were generated per sample. The trimmed sequence reads were analyzed using the QIIME pipeline and operational taxonomic units (OTU) were generated at 97% cutoff using BLASTn and compared to the curated database at the ribosomal database project (DeSantis et al. 2006).

Metabolomic analysis of mice wounds

Filtered wound tissue homogenates were ethyl acetate extracted prior to analysis by a nano LC-MS system (Acquity, Waters, Milford, MA, USA) according to the standard protocol

established by NCNPR. The reversed phase analysis was performed using an Acquity UPLC BEH C_{18} column (2.1 × 150 mm, 1.7 μm) with the injection volume of 5.0 μL. The mobile phase was consisted of solvent A and solvent B that contain water with 0.05 % formic acid and CH_3CN with 0.05% formic acid respectively. The flow rate for BEH-C_{18} column was 0.2 mL/min in gradient mode and gradient elution from 1% to 100% CH_3CN in H_2O. Gradient solvent system starts from solvent B 1% to 100% in 25 mins, then wash the column with solvent B 100% until 30 mins. The separated compounds were detected by a diode array detector (Agilent technologies, CA) of the UV wavelength of 220, 254, 325 and 380 nm. MS/MS studies were conducted by positive and negative electrospray ionization (ESI) conditions with scan mode of *m/z* of 100-150.

Statistical analysis

Statistical significance was determined by Student's *t* test or one way ANOVA. *P* values of <0.05 were considered significant.

4. Results

Characterization and antimicrobial activity of *Bacillus* spp strains

A total of five *Bacillus* spp. strains AP143, AP183, AP191, AP218 and AB01 showed strong *in vitro* antimicrobial activity against a number of bacterial and fungal pathogens (Table 1). The anti-MRSA activity of *Bacillus* spp. strains was confirmed by soft agar overlay and drop assay (Figure 1). Strains AP143, AP183, AP191 and AP218 were initially isolated from the plant rhizosphere as PGPR strains that can inhibit phytopathogens and promote plant growth. Each of the *Bacillus* spp. strains that exhibited inhibitory activity to MRSA strain 30 was capable of endospore formation. A phylogenetic analysis based on 16S rRNA and *gyrB* gene sequences of each of the *Bacillus* isolate indicated that four of the *Bacillus* strains were within the *B. subtilis*

group (inclusive of *B. amyloliquefaciens*). The *gyrB*-based phylogenetic approach demonstrated that strain AP183 is affiliated with *B. amyloliquefaciens* subsp. *plantarum* with strong bootstrap support (Figure 2). The phylogenetic affiliation of strain AP191 was determined as *B. methylotrophicus.*

In vitro antibacterial activities of _B. amyloliquefaciens_ subsp. _plantarum_ strain AP183

Using a double-dilution method, culture supernatant of AP183 was screened for *in vitro* antibacterial activity against *S. aureus* strain Xen29 (Figure 3) with IC_{50} of <1/32th dilution. The expression of secondary metabolites active against MRSA during a time course of bacterial growth was determined and it was found that AP183 strain starts to produce anti-MRSA compounds as early as 8 hours post-inoculation into TSB at 30°C and shaking with aeration at 200 rpm.

The extraction methods including different resin treatments and organic solvent partitioning were also investigated at the NCNPR for efficient recovery of anti-MRSA activity from supernatants and cell lysates by growing bulk cultures (≥1L) in appropriate growth conditions. The solvent partitioning method was the most effective extraction method. For example, the ethyl acetate extract of the supernatant showed IC_{50}s of 18.0 and 7.7 µg/mL against *S. aureus* ATCC 29213 and MRSA ATCC 33591, respectively. The methanol extract of the AP183 cell pellet also showed potent activity with IC_{50}s of 7.7 and 13.5 µg/mL, respectively, against *S. aureus* ATCC 29213 and MRSA ATCC 33591 (Figure 4). Preliminary fractionation of the ethyl acetate extract by reversed-phase silica gel chromatography generated 16 fractions, with the 9^{th} fraction being the most active with IC_{50} values of <1.1 µg/mL against the two tested strains (Figure 5). This activity-enriched fraction was predicted to contain a new compound (Ravu et al. 2015).

LC-MS analysis of the supernatant and cell lysate of *B. amyloliquefaciens* strain AP183

A correlation between the assays using the volume-based liquid culture supernatant and the weight-based solid extracts was established at the NCNPR. LC-MS analysis indicated that the two extracts displayed similar chemical profiles and the known antibiotics surfactins, iturins, and fengycins that are previously discovered from *Bacillus* spp. were also identified in this strain (Figure 6). Since the three classes of antibiotics are weakly active against *S. aureus* and MRSA, which has been confirmed by testing the commercially available surfactins and iturins in our assays, the potent activity of the AP 183 extracts suggested the presence of new antibiotic compounds.

Identification and structure determination of a novel antibacterial compound

Scale-up fermentation of a 30 L culture at the NCNPR led to the isolation of a new microcyclic polyene antibiotic, designated bacillusin A. The structure of bacillusin A was assigned by interpretation of NMR and MS spectroscopic data as a novel macrodiolide composed of dimeric 4-hydroxy-2-methoxy-6-alkenyl-benzoic acid lactones with conjugated pentaene-hexahydroxy polyketide chains (Figure 7). The presence of conjugated aromatic-pentaene system as indicated by LC-MS suggests that bacillusin A is chemically unstable in organic solvents (Figure 8). Additional compounds with the same molecular weight were detected when bacillusin A was allowed to stand at room temperature or even at 4^{o}C for a few days (Figure 8). Reduced antibacterial activity was also observed when bacillusin A was stored in DMSO for more than one week.

***In vitro* antibacterial activities of bacillusin A**

Bacillusin A showed strong *in vitro* antibacterial activities against multiple drug-sensitive and -resistant *S. aureus* and *Enterococcus* spp., and its potency was compared against vancomycin, ciprofloxacin, and methicillin (Table 2).

Bacillusin A exhibited a minimum inhibitory concentration (MIC) of 0.6 µg/mL against *E. faecium* ATCC 700221, which is was resistant to three of the aforementioned antibiotics tested at100 µg/mL. Another significant feature is that bacillusin A is a bactericidal compound exhibiting antibacterial activity at extremely low concentrations. Bacillusin A shows an IC_{50} of <0.02 µg/mL against the clinical isolate MRSA strain 30 compared to 0.2, 29.4, and 10.1µg/mL for vancomycin, ciprofloxacin, and methicillin, respectively (Table 2).

Whole genome sequencing of strain AP183

To determine the genomic basis of antibacterial mechanisms, the genome of AP183 was sequenced by Illumina Miseq sequencing technology. The sequence reads were trimmed for quality and assembled using the CLC Genomics Workbench (CLC bio, Cambridge, MA), obtaining 1,331,792 sequence reads, with an average coverage of 36×. *De novo* assembly of strain AP183 genome sequences resulted in 40 contigs larger than 500 bp, with an N50 of 190,739 bp, and the largest contig was 541,177 bp.

The estimated genome size was ~3.99 Mbp, with an average G+C% of 46.4%. The genome contains a total of 4,005 predicted open reading frames (ORF), of which 74% had a significant BLAST hit (E value of 0.001). The RAST server predicted 41 tRNA genes in this genome. It was found that the genome of AP183 contains two genes predicted to encode resistance to the antibiotics fosfomycin and fluoroquinolone, but no genes were predicted to encode virulence factors within this genome.

Gene clusters encoding secondary metabolite biosynthesis in strain AP183

Analysis of the AP183 contig sequences using the antiSMASH2.0 secondary metabolite prediction program suggested that AP183 encodes 18 predicted secondary metabolite biosynthesis gene clusters containing a total of 566 genes (Figure 9). AP183 is predicted to encode five trans-acyltransferase (AT) polyketide synthases (PKS), three nonribosomal peptide synthetases (NRPS), two hybrid PKS-NRPS, one hybrid trans-AT PKS, one type I PKS, one type II PKS, one type III PKS, and two terpene and two bacteriocin biosynthesis gene clusters. The trans-AT PKSs have emerged recently as an important group of biosynthetic enzymes involved in the production of many structurally complex, bioactive compounds. In 1993, bacillaene 1 was identified as the first member of the products of trans-AT PKS from the genome of *Bacillus subtilis* 168 (Piet 2009; Matilla et al. 2012). Since then, a number of clinically used antibiotics, mupirocin, virginiamycin M and anti-cancer agent bryostatins A were identified to be the products of trans-AT PKS enzyme (Davison et al. 2014). Although we have not yet confirmed the biosynthetic route of bacillisin A, its structure suggests a polyketide origin. We hypothesized that a trans-AT PKS biosynthetic gene cluster could potentially be involved in the synthesis of bacillusin A.

The AP183 genome is also predicted to contain a cluster with ORFs with homology to genes in the bacilysin biosynthetic cluster. In addition, an NRPS biosynthetic gene cluster was predicted in the AP183 genome with no known homology to that of other *Bacillus* species but with homologs to the genome of *Cyanothece* spp. strain PCC 7424.

Antibiotic resistance of AP183

Antibiotic resistance analysis revealed that the strain AP183 is susceptible to most of the tested antibiotics to varying degrees except colistin. It is highly susceptible to ampicillin, chloramphenicol, cephalothin and erythromycin (> 25mm diameter inhibition zone). Antibiotics

kanamycin, rifampin and sulfadiazine also inhibited their growth effectively (15-20mm zones of inhibition) whereas penicillin, vancomycin, novobiocin, neomycin, spectinomycin, gentamicin, ciprofloxacin and nalidixic acid showed moderate inhibition (10-15mm zones of inhibition).

***In vivo* cutaneous wound challenge**

Preliminary *in vivo* studies demonstrated that direct administration of AP183 spores to wounds significantly inhibit *S. aureus* Xen29 growth. A 46.91% reduction in the number of viable *S. aureus* cells was observed in response to AP183 spores application when the wound tissue was homogenized and plated for CFU numbers (Figure 10). Similarly, spores of AB01, AP143, AP191 and AP218 also showed anti-MRSA activities with this *in vivo* model.

The novel chemical structure, *in vitro* and *in vivo* antibacterial activities of AP183 was the basis for further use of this strain in mouse model to understand the mechanisms of its antibacterial action. We have found that applications of AP183 spores alone are capable to reduce *S. aureus* growth. However, the effectiveness was enhanced by including both the spores and the metabolites expressed by AP183 (Figure 11 A and B). Our *in vivo* results with more than 10 replicates demonstrated a significant inhibition of *S. aureus*-derived bioluminescence (Figure 12 A and B) as a result of AP183 spore and metabolite application ($P < 0.05$). Furthermore, we observed a significant 69.5% reduction in the number of viable *S. aureus* cells in response to AP183 and metabolite application when the wound tissue was homogenized and plated for CFUs (Figure 13).

We observed little or no bioluminescence associated with injection sites that contained both viable AP183 spores and secondary metabolites (Figure 12 A). These results were consistently observed with >10 mice and no incidence of inflammation, rash, or skin discoloration

at the site of injection were observed when animals were injected with AP183 spores and/or its associated metabolites.

Microbial diversity analysis of the mouse skin

In addition to identifying a beneficial bacterium capable of inhibiting MRSA growth, it was desired to find a probiotic strain that does not indiscriminately inhibit a broad spectrum of skin-associated microbiota. Therefore a culture-independent approach was adapted to determine the percent relative abundance of bacterial genera present in each treatment group. Our results indicated that the microbial community associated with an active *S. aureus* infection was dominated by *S. aureus*, and that the administration of AP183 and its metabolites resulted in a significant reduction in *S. aureus* percent relative abundance (Figure 14). Furthermore, inoculation of AP183 and its metabolites increased the relative abundance of other skin-associated bacterial taxa. These other residents of the mouse skin microbiome were not detected in the absence of AP183 inoculation, suggesting the growth promotion of other members of skin microbiome,

Metabolomic analysis of wound

The original LC-ESI-MS of both positive and negative detection chromatograms indicated the presence of surfactins from the mouse tissues after administration of AP183 and its metabolites. The compound was detected with retention time of ~26 min and molecular weight of 1035 (Figure 15). However, we were unable to detect other metabolites such as iturins, fengycin and bacillusin A from mice wounds.

5. Discussion

The results of this study led to the identification of *B.amyloliquefaciens* subsp. *plantarum* strain AP183 as a promising probiotic candidate for preventing skin infection caused by MRSA. Although *S. aureus* can cause life-threatening systemic infection, skin and soft tissues are the most common sites of *S. aureus* infection. It comprises more than 75% of MRSA-related diseases (Cohen et al. 2007). Inhibition of the colonization of MRSA on skin could prevent the bacteria entering the bloodstream and ultimately reduce the occurrence of sepsis.

Through screening of 277 *Bacillus* strains for *in vitro S. aureus* inhibition, and conducting preliminary studies using a mouse wound model, it was observed that *B. amyloliquefaciens* strain AP183 was the most effective inhibitor of pathogenic *S. aureus* growth. The antibacterial activity of AP183 is partly due to the production of secondary metabolites. In this study AP183 was found to produce a novel antibiotic, bacillusin A that exhibits strong *in vitro* activities against MRSA and vancomycin resistant *E. faecium* (Ravu et al. 2015). Bacillusin A is a newly discovered macrocyclic polyene antibiotic composed of dimeric 4-hydroxy-2-methyl-6-alkenylbenzoic acid lactons with conjugated pentaene-hexahydroxy polyketide chains.

A review of the literature suggests that bacillusin A is structurally analogous to marinomycins A-D that was isolated from a marine Actinomycete, *Marinispora* (Kwon et al. 2006) and SIA7248 isolated from the marine isolate *Stretomyces* sp. A7248 (Zou et al. 2013). Compared to the marinomycins and SIA7248, bacillusin A possesses a larger macrocyclic ring with four additional C2 extender units, making it more difficult to determine the absolute or even relative configuration for the stereogenic carbons. Several attempts to crystallize bacillusin A in different organic solvents for X-ray crystallography failed, partly due to the limited amount of purified compound obtained from the isolation process. The limited amount (0.247mg/L) of compound prevented chemical derivatization that may provide further stereochemical

information. In addition, bacillusin A was found to be chemically unstable in organic solvents as indicated by LC-MS analysis. Additional compounds with the same molecular weight were detected by LC-MS when bacillusin A was allowed to stand at room temperature or even at 4^{o}C for few days. This is similar to marinomycin A that can be photoisomerized to marinomycins B and C with reduced antibacterial activities through the conversion of the *trans* double bond attached to the aromatic ring to a *cis* double bond when exposed to light (Kwon et al. 2006). This isomerization and possible decomposition during the isolation process resulted in a low isolation yield of the compound (0.247 mg/L). It was also observed that the antibacterial activity of bacillusin A decreased when it was stored in DMSO at 4°C for more than one week. The biochemical instability of this compound might be medically beneficial in the use of these antibiotics to protect against bacterial infections, e.g., infected wounds where rapid elimination of antibiotic residues can be an advantage.

The primary objective of this research project was to identify beneficial bacterial strain that can be applied as a probiotic to inhibit skin infections caused by MRSA and restored beneficial skin microbiota. A probiotic can be used either internally or externally to restore the balance of beneficial microorganisms to pathogen. The key considerations for use of a beneficial bacterium must be safety and efficacy. For these reasons we have focused on identifying endospore-forming members of the genus *Bacillus* that have efficacy in preventing *S. aureus* infections, without any known potential for pathogenicity. Specifically, this study focused on identifying gram-positive *Bacillus* strains that lack endotoxin or other known virulence factors and were highly effective at inhibiting *S. aureus* growth under *in vitro* conditions. This led to the discovery of a specific strain, AP183, which is the leading candidate for a skin probiotic for MRSA inhibition. The annotation of the genome sequence of the AP183 strain revealed the

absence of predicted virulence factor encoding genes in this genome which supports the safety of this strain for topical application. Further studies of repeated applications of strain AP183 in mouse and minipig models of MRSA inhibition should be conducted for safety assessment, along with studies to assess any cytotoxicity of AP183 secondary metabolites (e.g., bacillusin A).

Strains of *B. amyloliquefaciens*, as members of the *B. subtilis* group, have been used previously as probiotics in animals and plants and are not associated with disease (Ahmed et al. 2014, Gonzalez-Ortiz et al. 2013). There are many strains of *B. amyloliquefaciens* already developed for use with crops, livestock or products for human consumption (Krober et al. 2014, Lee et al. 2012), and *Bacillus* spores are currently been using topically to prevent infections caused by yeast, fungus, bacteria or Herpes simplex virus (Farmer and Mikhail 1998). Farmer and Mikhail (Farmer and Mikhail 1998) described the potential use of *Bacillus* spores for the prevention and control of bacterial infections, wherein spores of *B. coagulans* inhibited growth of *S. aureus* in skin. The key differences with the previous study is the use of a different species of *Bacillus* (*amyloliquefaciens* strain AP183) and the observation that the use of *Bacillus* spores alone is not sufficient to inhibit the establishment of MRSA, whereby this strain also requires the presence of AP183 metabolites. The proposed mechanisms of action include both direct inhibition of *S. aureus* growth and viability due to the expression of multiple secondary metabolites, as well as competitive inhibition of *S. aureus* growth. Since *S. aureus* and other pathogens are fast-growing (i.e., r-selected) bacteria that can outcompete many potential probiotic strains, this study specifically selected endospore-forming, fast-growing *Bacillus* spp. that are well-adapted at competing for limited C substrates within the skin microbiome, but without the potential for virulence. Similar to the gut microbiome, the skin microbiome can play an important role in preventing skin infections primarily by inhibiting colonization and biofilm

formation. Iwase et al. (Iwase et al. 2010) demonstrated the role of serine protease secreted by *Staphylococcus epidermidis*, a skin commensal bacterium, inhibits biofilm formation and colonization of *S. aureus*. Therefore it is important to restore the balance of normal skin residents that can confer better protection against pathogenic microbes.

The mice microbiome studies indicated that the inoculation with AP183 and its metabolites significantly reduced the relative abundance of *S. aureus* and also increased in the relative abundance of other skin-associated bacterial taxa. These other residents of the mouse skin microbiome were not even detected in the absence of AP183 inoculation, and could conceivably play an important role in maintaining skin microbiome conditions that do not facilitate *S. aureus* infectivity. Although AP183 inoculation completely hinders symptoms of *S. aureus* Xen 29 infectivity at the wound site, it was still possible to detect *S. aureus* cells using both culture-based and culture-independent methods. Perhaps the *S. aureus* cells that remain in the wound site after exposure to AP183 and its metabolites are in a viable but quiescent state, such that they remain capable of growth when plated onto a rich culture medium, but may not be expressing virulence factors or be in a metabolically inactive state within the mouse.

The culture-dependent and metabolomic analysis of mouse wound revealed that strain AP183 can grow and produce potent secondary metabolites that inhibit MRSA infectivity in mice. However, by using LC-MS analytic methods it was only possible to detect the major metabolite surfactin in wound samples. It is reasonable to conclude that other metabolites such as iturins and bacillusin A might have been produced, but were not detected due to the short-half life of the compound or the inherent detection limits. Thus, future research to develop an efficient and sensitive analytic system for skin metabolome analysis will be of special interest.

Taken together, our findings indicated that AP183 spores and metabolites hinder *S. aureus* colonization *in vivo* through a novel mechanism of bacterial interference, which could lead to the development of innovative therapeutics to prevent *S. aureus* colonization and infection in skin.

Table 1. Antimicrobial activity of five different Bacillus spp.strains against fungal and bacterial pathogens (IC50 µg/mL).

Taxonomic affiliation	Strain	Source of isolation	*Candida albicans*	*Cryptococcus Neoformans*	*S.aureus*	MRSA	*E. coli*	*Pseudomonas aeruginosa*

Chapter 4

Functional screening of a large-insert soil metagenomic library for the discovery of antibacterial compounds.

1. Abstract

The emergence of multidrug-resistant pathogens has increased the need for the discovery of novel antibiotics. Soil microbial communities are known to be a great resource for natural products but a majority of them have not been explored for their secondary metabolite synthesis because many of them are unculturable using currently available laboratory techniques. We cloned high molecular weight DNA from the microbial assemblage from the Cullars Rotation agricultural soil (a plot without N or P amendments) into a shuttle bacterial artificial chromosome (BAC) vector. The soil metagenomic library is comprised of 19,200 *E. coli* clones with an average insert size of 110 kb. The large insert size and broad host range of this library are designed to overcome some of the limitations commonly encountered in using functional metagenomics for natural product discovery. We screened all of the *E. coli* clones for inhibition of growth of methicillin-resistant *Staphyloccocus aureus* (MRSA) using a 96-well microtitre plate format. *In situ* lysis of the *E. coli* host enabled detection of both intra- and extracellular compounds, yielding a total of 28 anti-MRSA clones. Transformation of naïve *E. coli* with BAC DNA isolated from anti-MRSA clones confirmed the presence of their anti-MRSA activity. Sequencing and sub-cloning of these clones revealed genes predicted to be involved in various biosynthetic pathways as well as many genes with unknown functions. Interestingly, we observed that multiple clones (n=7) were capable of modifying chloramphenicol that was added to the *E. coli* culture medium, thereby resulting in modification of an existing antimicrobial scaffold. LC-MS analysis of the organic extract of the clones revealed three new

chloramphenicol derivatives. Chemically synthesized chloramphenicol derivatives tested separately did not show strong antibacterial activities against *E. coli* or *Pseudomonas aeruginosa*; however, they showed antibacterial activity against MRSA, *Mycobacterium intracellulare* and *M. tuberculosis* with MICs of 27.6, 12.5 and 50.0 μg/mL, respectively. These results demonstrate that large-insert soil metagenomic libraries can be screened using innovative functional screening methods to access previously undescribed genomic and biochemical diversity.

2. Introduction

Infectious diseases continue to be a significant global public health concern and have been a cause of concern with the emergence of hyper-virulent and multidrug resistant (MDR) bacterial pathogens (Jones et al. 2008). The rising prevalence of drug-resistant pathogens (Rossolini et al. 2014; Davies et al. 2010) threatens a return to the pre-antibiotic era in which infectious diseases are not going to be cured using any available treatment. The increasing antimicrobial resistance among *S. aureus* isolates and their ability to produce biofilms in tissues and medical devices limits treatment options (Archer et al. 2011). Vancomycin, a glycopeptide antibiotic, is the first choice of drug for the treatment of MRSA infections. However, its application is limited by the emergence of strains with reduced antimicrobial susceptibility (Howden et al. 2010) and the occurrence of vancomycin treatment failure and mortality in patients with methicillin-sensitive *S. aureus* (MSSA) bacteremia (Lodise et al. 2008; Soriano et al. 2008). The minimum inhibitory concentration (MIC) creep, the incremental vancomycin MIC, is a frequently observed phenomenon in MRSA infected patients with vancomycin treatment (Steinkraus et al. 2007). Until now, 12 vancomycin-resistant MRSA strains have been identified in the Unites States and comparative genomics of all 12 strains revealed that they are

belonged to the clonal cluster 5 (CC5) lineage (Kos et al. 2012). Wide spread use of vancomycin for the treatment of MRSA infection has led to the emergence of two types of glycopeptide-resistant (Tarai et al. 2013) *S. aureus* strains that include glycopeptide-intermediate-resistant *S. aureus* (GISA) and vancomycin-resistant *S. aureus* (VRSA). In addition to antibiotic resistance to vancomycin, side effects caused by vancomycin treatment are also another impediment to treat MRSA infections. Several new alternative antibiotics such as daptomycin, linezolid and tigecycline are in use to treat MRSA-infected patients (Micek 2007). However, their application efficacies are limited by the different varieties of infection caused by MRSA (Liu et al. 2011). The three newest drugs oritavancin, dalbavancin and tedizolid have recently been approved by FDA for treating MRSA infections (Network 2014). However, these new drugs can only be used for skin and skin structure infection and nosocomial pneumonia (NP). Since the applicability of these antibiotics are limited to only two types of MRSA infections, the need for discovering novel antimicrobial compounds is urgent to combat this MDR bacterial pathogen (Levy et al. 2004; Fischbach et al. 2009).

A vast number of antibiotics in use today to treat patients with infectious diseases are derived from soil bacteria or fungi (Newman et al. 2007). The metabolic and functional versatility of soil microorganisms makes the environment is a good source for the discovery of novel natural products, including antibiotics (Courtois et al. 2003). Classical methods for discovering antibiotics involve screening natural products (Reddy et al. 2014) or a chemically synthesized compound (Lawrence et al. 2011) against a target bacterial culture. More than 20 novel classes of antibiotics were developed in this way between 1930 and 1962 (Parsley et al. 2011; Yang et al. 2014) However, only two new classes of antibiotics have been marketed since then (King et al. 2009; Jenke-Kodama et al. 2009; Katoh et al. 2013). The past several decades

have experienced diminishing success rates for antibiotic discovery using a culture-based approach due in part to the >99% rate of antibiotic rediscovery (Piel, 2002)

New methods for drug discovery have been developed recently, including genome mining, novel culturing methods, and metagenomics (Wilkinson et al. 2007; Ling et al. 2015; Nikolouli et al. 2012)). Decoding the genomes of antibiotic producing microbes has revealed the presence of large numbers of new pathways (Bentley et al. 2002; Wilkinson et al. 2007; Nikolouli et al. 2012). Bioinformatic analysis of most antibiotic-producing microbial genomes indicates the presence of multiple pathways for secondary metabolite biosynthesis. However, these cryptic pathways are mostly silent and efforts to turn them on have succeeded, but not as a large scale platform (Lewis, 2013). New cultivation strategies using diffusion chambers to mimic the natural entrainment have been employed recently to cultivate as-yet uncultured bacteria (Ling et al. 2015). Using this technique, a new class of antibiotic, teixobactin, was discovered after screening 10,000 soil bacteria isolated using *in situ* cultivation methods (Ling et al. 2015). This approach, while successful in identifying novel cultured isolates that may synthesize novel compounds, is known to have a relatively high rate of failure for maintaining isolates in culture (about 20-30% can be maintained in laboratory culture) and these cultured isolates do not represent the full extant diversity of microbial life present in natural environments.

Another recent strategy for drug discovery is metagenomic analysis of uncultured microbes, allowing analysis of the collective genomes of all the resident organisms (Handelsman et al., 1998; Rondon et al., 2000). Metagenomic libraries are constructed by extracting environmental DNA (eDNA) directly from environmental sources such as soil (Sangwan et al. 2012), sediments (Havelsrud et al. 2011), activated sludge (Liaw et al. 2010), and hot thermal vent sediments (Wemheuer et al. 2013). Because of the ability of metagenomics

to incorporate the DNA from diverse sources, this offers a tool to discover and exploit a wide variety of natural products (e.g., enzymes, metabolites) from previously uncharacterized microorganisms that reside in natural environments.

Functional profiling of metagenomic libraries has recovered novel biocatalysts and bioactive secondary metabolites (O'Brien et al. 2014; Dougherty et al. 2012; Gillespie et al. 2002), many of which would be impossible to acquire by using culture-based methods. Metagenomics has led to the isolation of natural products with enzymatic (Dougherty et al. 2012), anticancer (Pettit 2004) and antimicrobial (Gillespie et al. 2002; Banik et. al. 2010) activities. One study isolated a small molecule, called indirubin, from a soil metagenomic library (MacNeil et al. 2001), and later it was found that indirubin and its derivatives inhibit tumor growth by antitumor angiogenesis (Zhang et al. 2011). Chow et al. (Chow et al. 2012) have isolated and characterized two novel lipolytic enzymes using a functional metagenomics approach. A functional metagenomics approach, while successful in some cases, depends upon successful transcription, translation and in some cases post-translational modifications for a natural product to have activity, and this may limit the potential for heterologous expression of cloned genes in a particular host such as *E. coli*. Given that many biosynthetic pathways, such as polyketide synthases (PKSs), require large genomic regions for biosynthesis, this also is a fundamental limitation for studies that clone or directly sequence smaller genomic fragments.

In this study a functional metagenomic approach was employed to identify recombinant clones that inhibited MRSA growth. A large-insert soil metagenomic library was constructed in an inducible-copy bacterial artificial chromosome (BAC) vector and these recombinant clones were heterologously expressed in *E. coli* strain DH10B and screened for clones that elaborate an antibacterial activity. There is a potential benefit of screening a larger-insert metagenomic library

for antimicrobial activity due to the higher probability that a recombinant clone will contain an intact biosynthetic pathway necessary for the synthesis of a new chemical entity (NCE). The use of BAC vectors for constructing metagenomic library has facilitated large-insert cloning of environmental DNA (Wang et al., 2013) and the expression of eDNA can be enhanced by using a copy-inducible plasmid. The copy-inducible plasmid contains an origin of replication (i.e., *oriV*) that is under the control of an arabinose-responsive promoter, therefore each recombinant clone is represented multiple times within each host cell (Wild et al., 2002; Kakirde et al., 2010). The innovations in this study include the use of high molecular weight metagenomic DNA from soil microbial communities for construction of large-insert BAC libraries and using an "*in situ* lysis" method to screen metagenomic libraries for antibacterial activities. The antimicrobial expressing metagenomic clones identified in this study may be promising candidates as therapeutants to control MDR pathogens.

3. Materials and methods

Metagenomic library construction

For constructing a large-insert containing metagenomic library, high molecular weight **(**HMW) environmental DNA was isolated from the Cullars Rotation soil (Auburn, AL), a agricultural plot that had not been amended with fertilizers for the past 100 years (Mitchell et al. 2012). The isolation and purification of soil HMW DNA was conducted by the protocol published previously (Liles et al. 2008) with some modifications. Briefly, random shearing approach was used to acquire the desired size range (>1 Mbp) of soil DNA fragments for cloning into a BAC vector. The sheared DNA was then blunt ended, ligated into the pSMART BAC-S vector (Figure 1) (Zhou et al., manuscript in preparation) and transformed into the host *E. coli* strain of choice. Clones were cryopreserved in 384 well plates at -80°C.

Metagenomic library screening for antibacterial activity

An *in situ* method was used for high-throughput screening of the metagenomic clones for activity against clinical MRSA strain. In this method, the BAC library containing *E. coli* cell growth and lysis, as well as MRSA growth and inhibition assay, were all performed in the same well of a 96-well plate. The library in a 384-well format was inoculated into 96-well plates by using a pin replicator. The *E. coli* clones were grown for 48 hours at 37°C in Luria-Bertani (LB) medium containing 12.5 µg/mL of chloramphenicol (Cm) and 0.01% arabinose to induce plasmid copy number, and then plates were frozen at -80°C followed by rapid thawing at 55°C, thereby lysing most *E. coli* cells. Each well was then inoculated with 100µL of 1:1000 diluted log-phase culture of a clinical MRSA strain 30 (East Alabama Medical Center, Opelika, AL). The medium also contained nalidixic acid (30µg/mL) to inhibit the growth of any remaining *E. coli* cells and the MRSA culture was grown for 24 hours at 37°C. Finally, 165 µL of the viability indicator solution of resazurin (0.02%) was added to each well and the plates were incubated at 37°C until color change was observed from blue to pink for the majority of wells (Martin et al. 2003). In the resazurin-based bioassays, fluorescence readings of reduced resazurin (resorufin) were recorded (530 nm excitation and 590 nm emission) using a fluorescent microtitre plate reader (BioTek, Winooski, VT) and used for calculating the % growth inhibition of the tester culture in comparison with the empty vector negative control.

Validation of recombinant clones with antibacterial activity

Each recombinant clone that inhibited the growth and/or viability of the MRSA strain 30 from the primary screening was re-tested to verify the antibacterial activity against MRSA. To validate anti-MRSA activity of putative positive clones, *E. coli* cultures from the original 384-well plate were grown for colony isolation on LB agar plates containing 12.5µg/mL Cm

without arabinose in order to maintain the vector at single copy. Six independent colonies from each positive clone were tested for anti-MRSA activity as described above. Clones that tested strongly positive in this secondary screen were re-tested twice. Those that tested positive in three consecutive assays were further characterized to identify the best lead candidates.

Preliminary characterization of active clones

A total of 28 clones were selected for further testing to characterize the active compounds produced by these clones. Supernatants from 28 anti-MRSA compound-producing clones were analyzed at the National Center for Natural Product Research (NCNPR, Oxford, MS) according to the standard protocol established by the NCNPR. Silica gel chromatography of an ethyl acetate extract of the supernatant of eight metagenomic clones resulted in the identification of eight different chloramphenicol derivatives (Cm derivatives). The structural elucidation of these compounds was achieved by NMR and MS analyses at the NCNPR.

DNA sequence generation and analysis

Each of the 28 antibiotic-expressing clones were selected for complete insert sequencing using either 454 pyrosequencing (454 Life Sciences, Branford, CT) or an Ion Torrent PGM (Life Technologies, Grand Island, NY). Large-scale BAC DNA was isolated from each respective clone using an alkaline lysis method (Sambrook and Russell, 2001) and extracted DNA was used to generate bar-coded shotgun subclone libraries for 454 pyrosequencing at the Lucigen Corp. (Middleton, WI). The 454 pyrosequencing and Ion Torrent PGM was conducted at the Lucigen Corp. (Middleton, WI) or at EnGenCore at the University of South Carolina (Columbia, SC) respectively, using a Genome Sequencer FLX system as per the manufacturer's instructions. The sequences were trimmed and assembled *de novo* into contiguous fragments (contigs) using the CLC genomics workbench (Cambridge, MA). The contig(s) that represented the complete (or

nearly complete) clone insert DNA was exported in FASTA format. The protein-coding Open Reading Frames (ORFs) within the inserts of the BAC DNAs were predicted using GeneMark (Lukashin and Borodovsky 1998) and the ORF sequences were compared against the GenBank nr/nt database using BLASTx and BLASTn search algorithms to predict the function of putative gene products.

Insert size determination for metagenomic clones

The insert size of clones was determined by complete insert sequencing and restriction digestion. A large-scale BAC DNA isolation was conducted for clones P6B5 and P335B14 according to methods described previously (Sambrook and Russell 2001). Purified BAC DNA was restriction digested with NotI (New England BioLabs Inc. MA) enzyme according to the manufacturer's instructions and resolved the RFLP pattern using pulsed field gel electrophoresis with a 1 to 15 second switch time at 6 V/cm on a CHEF gel (BioRad, Hercules, CA).

Subcloning of clones P6B5 and P35B14

Anti-MRSA clones P6B5 and P335B14 were characterized using sub-cloning to identify the ORF(s) responsible for anti-MRSA activity. The following strategy was used to sub-clone the clones P6B5 and P35B14 to identify the genetic regions responsible for anti-MRSA activities. A large-scale BAC DNA isolation was conducted for clones P6B5 and P335B14 according to methods described previously (Sambrook and Russell 2001). Approximately 20 µg of BAC DNA from each clone was sheared using a g-TUBE (Covaris, MA) to obtain fragmented DNA within the range of 4 to 8 kb. Fragmented DNA was separated using gel electrophoresis and DNA of the targeted size was excised for purification. The ends of the fragmented DNA obtained by shearing were repaired using a DNA Terminator kit (Lucigen, WI). End-repaired DNAs from both clones were ligated into the pSMART vector (Lucigen, WI) and then electroporated into

electrocompetent *E. coli* (*E. coli* 10G) cells harboring pGNS-BAC to provide Cm-resistance. Sub-clones were selected on LB agar supplemented with 200 µg/mL ampicillin and 12.5 µg/mL Cm. The transformants were picked robotically using a QPix2 (Molecular Devices, Sunnyvale, CA) in 96-well plates and were grown overnight with shaking at 200 rpm at 37^{o}C. All the cultures grown in shallow 96-well plates were transferred to deep-well plates and their anti-MRSA activity were determined according to the method described above. Sub-clones with anti-MRSA activity were grown for plasmid extraction and the ORF(s) contained within active sub-clones were identified by primer walking PCR (Table 1) followed by sequencing. The size of the insert within positive sub-clones was determined by PCR using vector-specific primers.

Cloning of *trfA* gene into pSMART BAC-S vector

The *trfA* gene from clone P6B5 was PCR amplified using custom designed primers AF-BstXI (5'-GCTTCGGATCCCAGTCACTGCGTCTT-3') and AR-BstXI (5'-ATGCATGCATGCCTGGTCGCCAGCAA-3') that included BstXI restriction sites at their 5′ end. PCR product of *trfA* gene and empty vector (pSMART BAC-S) were restriction digested with the BstXI (New England BioLabs Inc. MA) enzyme. Digested products were gel purified and concentrated with DNA clean and concentrator^{TM}-5.0 (Zymo Research, CA) according to the manufacturer's instructions. The purified *trfA* gene amplicon was ligated with the pSMART BAC-S vector using quick ligase (New England BioLabs Inc. MA) and the resulting ligation mixture was transformed into *E. coil* strains DH10B (genotype F- mcrA Δ(mrr-hsdRMS-mcrBC) endA1 recA1 Φ80dlacZΔM15 ΔlacX74 araD139 Δ(ara,leu)7697 galU galK rpsL nupG λ- tonA) and into "E. cloni 10G" (Lucigen Corp.., Middleton, WI) that is a derivative of DH10G that contains the arabinose-inducible *trfA* gene on the chromosome, by electroporation (1 mm gap cuvette, 1.8 kV, 600 Ohms, 10 µF). The clones were selected on LB agar plates containing 12.5

μg/mL of Cm and the presence of *trfA* was confirmed by PCR using vector and *trfA* gene specific primers (AF-BstxI and TRA-IntR; AR-BstxI and TRA-IntF). The phenotypic characteristics of transformants were evaluated with or without arabinose induction using different concentrations of Cm (12.5, 25, 30, 40, 50, 60, 70, 80, 90, 100, 120, 150 and 200 μg/ mL). The plasmid DNAs were extracted after normalizing the optical density of the overnight culture (OD_{600} 0.7) using an alkaline lysis method and the plasmid yields were compared with that of negative control by agarose gel electrophoresis.

4. Results

Library screening for identification of antibiotic-producing clones

Initial screening of the metagenomic library with approximately 19,200 clones in the identified a total of 136 clones with some degree of inhibition of MRSA viability (Figure 2). Multiple bioassays were conducted to isolate a set of clones that were consistently positive for anti-MRSA activity. After several rounds of validation experiments, 28 top candidates were selected for the next phase of biochemical and genetic characterization. It was revealed that growing clones in 96-well plates compared to growth in culture tubes gave comparable results. The BAC DNA from each clone was transform into a naïve *E. coli* strain by electroporation, and transformants from each clone were tested for anti-MRSA activity. All 28 re-transformed metagenomic clones showed significant activity in inhibiting MRSA growth, demonstrating that the cloned DNA in *E. coli* was necessary and sufficient to confer antimicrobial activity against MRSA.

DNA sequence analysis

The sequences of inserts from all 28 anti-MRSA expressing BAC clones were determined using bar-coded next generation sequencing. After trimming and assembly *de novo*, the BAC DNA insert sequences showed that the average inserts sizes are about 113 kb. Contigs that represented the entire clone insert with > 50× coverage were selected for analysis. The number of predicted ORFs in each of the clones was more than 100 ORFs for most clones. A large number of ORFs were predicted to encode proteins with unknown functions, which makes it difficult to predict the specific gene(s) required for expression of their anti-MRSA activities. The BLASTx analysis of the ORFs found within the metagenomic clones revealed a diverse array of protein-coding genes with homology to that of diverse bacterial taxa (Figure 3).

Determine the insert size of the metagenomic clone

The inserts size of the clones P6B5 and P35B14 were determined by BAC DNA extraction followed by restriction digestion and resolution pulsed-field gel electrophoresis (Figure 4). The RFLP pattern revealed that anti-MRSA clones P6B5 and P35B14 have approximate insert sizes of 2.4 kb and 45.0 kb respectively.

Characterization of Cm derivatives from metagenomic clones

LC-MS analysis revealed that seven positive metagenomic clones (P35B14, P22E10, P28I7, P37I10, P27M10, P6B5, and P5A4) that are active against MRSA had similar metabolic profiles (Figure 5). Cm (1) was identified in all seven clones with a retention time (t_R) of 6.37 min and similar isotopic patterns and UV spectra were observed for several compounds with longer t_R (e.g., compounds 2−9 in clones P6B5 and P35B14), indicating they were chlorine-containing Cm derivatives. Although Cm derivatives have been reported previously (Gross et al. 2002; Bizerra et al. 2011; El-Kersh et al. 1976), analogs producing some of these molecular ions were not present in current literature reports. Thus, clone P35B14 was selected for a scale-up

using fermentation and chemical isolation due to the presence of typical Cm derivatives as shown in the LC-MS chromatogram (Figure 5).

At the NCNPR, an ethyl acetate extract of the P35B14 clone fermentation broth was subjected to column chromatography on normal phase and reversed-phase silica gel to yield compounds 2−9, along with Cm (1). Compounds 2−6 were identified as 3-acetylchoramphenicol, 3-propanoyl chloramphenicol, 3-butanoylchloramphenicol, 1,3-diacetylchloramphenicol, and 1,3-dipropanoyl-chloramphenicol, respectively, by comparison of their NMR data and optical rotations with those reported in the literature. The structures of the new compounds 7−9 were established; compound 7 was isolated as a liquid and corresponded to the peak at t_R 11.39 min in the LC-MS chromatogram (Figure 5). Based on the NMR data analysis the structure of compound 7 was determined as 1-acetyl-3-propanoylchloramphenicol.

Compound 8 was also isolated as a colorless liquid and showed close similarities to compound **7** in terms of ^{1}H and ^{13}C NMR spectra. The ^{1}H and ^{13}C NMR data suggested that compound 8 had one acetyl group and one butanoyl group in the molecule and the structure of compound 8 was assigned as 1-acetyl-3-butanoylchloramphenicol.

Compound 9 had the least polarity among the eight compounds produced by this metagenomic clone. The ^{1}H NMR spectrum of compound 9 showed similarity to 1,3-dipropanoylchloramphenicol (6), and careful analysis of the ^{1}H NMR data concluded that a propanoyl and a butanoyl group were present in this molecule. 2D NMR correlations of compounds 7−9 were presented in Figure 6.

Using purified compounds as standards for LC-MS analysis, compounds 1−9 were confirmed to exhibit specific t_R in the seven metagenomic clones as shown in Figure 5. Monoacylated compounds 2−4 were major metabolites present in all seven clones, while

diacylated compounds 5−9 were observed in clones P35B14 and P6B5 that showed similar metabolic profiles. It was noted that compounds 6 and 8 were co-eluted at the same t_R 12.40 min. Compound 9 was a minor metabolite, present in clones P35B14, P6B5, and P5A4 was also co-eluted with an unidentified compound at t_R 13.19 min. The above analyses suggested that all seven of the metagenomic clones contain highly active acyltransferases that are able to acylate Cm.

***In vitro* antibacterial activities of Cm derivatives**

The seven Cm derivatives (2-7) isolated from metagenomic clones and the three synthetic analogs (10−12) were tested for antibacterial activity against, *E. coli*, and *Pseudomonas aeruginosa*. Results indicated that all Cm derivatives tested separately were inactive at a concentration of 200 µg/mL against these two pathogens, but chloramphenicol 3-acetate and tert-butyl dimethyl silyl chloramphenicol had activity against both methicillin sensitive and –resistant *S. aureus*. However, compounds 2, 4, and 10 showed strong antibacterial activity in an initial testing against *Mycobacterium intracellulare*. Compounds 1−7, 10−12, and 15−18 were tested for *in vitro* anti-*Mycobacterium* activity against *M. intracellulare* and the tuberculosis-causing strain *M. tuberculosis*. The results showed that *M. intracellulare* was more susceptible to all these compounds except compounds 5 and 7 with minimum inhibitory concentrations (MICs) ranging from 12.5 to 50.0 µg/mL. However, only compounds 10, 12, and 18 showed antibacterial activity against *M. tuberculosis* with MICs of 50.0 to 100.0 µg/mL (Table 2). It was also found that an aromatic-containing acyl substituent of compound 18 was the most active against *M. intracellulare* and *M. tuberculosis* with MICs of 12.5 and 50.0µg/mL respectively, in comparison with Cm (1) which was only active against *M. intracellulare* with an MIC of 25.0 µg/mL.

Subcloning of clones P6B5 and P35B14 for identifying gene(s) responsible for the antibacterial activity

The anti-MRSA compound(s)-producing clones P6B5 and P35B14 have approximate insert DNAs of 2.4 kb and 45.0 kb respectively, as estimated by restriction digestion followed by agarose gel analysis (Figure 4). Since the anti-MRSA activity of clones P6B5 and P335B14 were due to their cloned DNA inserts, therefore, the active compounds was expected to be encoded by an ORF(s) present within their inserts. To identify the ORF(s) responsible for the antibacterial activity, subcloning of BAC DNAs of clone P6B5 and P35B14 were performed in pSMART HC Amp vector (Lucigen Corp. WI). The subclones of P6B5 showed anti-MRSA activity but not the subclones of P35B14 and those active subclones were grown for plasmid extraction and sequencing to identify the ORF(s) required for anti-MRSA activity. The nucleotide sequence of this ORF was determined by primer walking and a single candidate gene, *trfA*, appeared to encode the antibacterial activity. This was apparently not the *trfA* gene present in the genome of the "*E. cloni*" host strain, as the nucleotide sequence of *trfA* gene showed 97% similarity to known *trfA* sequences of pGNS-BAC vector. In addition, the vector pSMART BAC-S did not have any *trfA* gene. These results collectively suggested that this gene may have been cloned from metagenomic DNA. The *trfA* gene encodes the TrfA replication protein and together with the *oriV* replication origin the TrfA and *oriV* are considered the mini-replicon for RK2 plasmids; therefore, when the origin is present on a plasmid (e.g., pSMART-BAC-S containing *oriV*) and with the *trfA* on the chromosome under control of an arabinose-inducible promoter, this allows the BAC copy number to be induced to approximately 50-100 copies per host chromosome (Westenberg et al. 2010). In this case, we hypothesized that the cloned *trfA* gene was not arabinose-inducible given that it was apparently cloned from an environmental source. To determine the effect of copy induction for Cm derivative generation, the *trfA* gene from clone P6B5 was PCR amplified and cloned into *E. coli* strains DH10B and "E. cloni 10G" (Figure 7).

The clone that contained *trfA* gene was confirmed by PCR (Figure 8) and screened for Cm resistance at a concentration ranging from 12.5 to 200 µg/mL. Results indicated that *E. coli* containing the empty vector were significantly resistant to the highest concentration (200µg/mL) of Cm as compared to the *trfA* containing clones (Figure 9) and the antibiotic resistance pattern was not dependent upon the addition of arabinose in the culture media. Arabinose induction of *trfA* was not expected in clone 9 (*trfA* containing clone in *E. coli* strain DH10B) since the *trfA* gene was cloned from metagenomic DNA.

5. Discussion

Function-based metagenomic approaches have enabled the discovery of active compounds without any previous knowledge of the DNA sequences encoding the biological functions, and have been successfully used to discover many classes of biocatalysts and bioactive secondary metabolites. Though a functional metagenomic approach has been successfully used for the isolation of antibiotics from soil metagenome (Gillespie et al. 2002) and for discovery of many other natural products, this approach also has unique challenges that can limit antibiotic discovery, such as cloning incomplete biosynthetic pathways, obtaining sufficient expression in a heterologous host, inefficient secretion of the antibiotic, and lack of detection of the antibiotic by a screening method. While many of these challenges are inherent in a functional metagenomic approach, in this study novel protocols were used to improve this approach for antimicrobial discovery. First, the metagenomic library used in this study was obtained using randomly sheared metagenomic DNA that resulted in large insert sizes (>110 kb) that increase the number of genes per clone and enhances the probability of cloning intact operons. Secondly, an *in situ* lysis method was used for high throughput library screening for clones expressing an

antibacterial activity that allowed for growth of the metagenomic cultures, lysis, and screening in the same 96-well plates, and detected both extra- and intracellular compounds.

One perceived advantage of using BAC vectors is the high stability of both the vector and the insert when maintained at a single or low copy and the ability to be induced to high copy number when required. The pSMART-BAC-S vector used in this study allows high-throughput conjugation-based transfer and stable maintenance of large-insert BAC clones into Gram-negative as well as Gram-positive hosts, with chromosomal integration or stable episomal maintenance for heterologous expression. As this was the first study in which this library was screened for heterologous expression, the original *E. coli* cloning host was first used for expression. Subsequent studies will investigate the expression of this library in other heterologous hosts. Present function-based analysis of metagenomic library revealed identifying soil-derived recombinant clones that showed growth inhibition of MRSA strain. The rate of identifying anti-MRSA clone from the library was 0.147% and some of the identified clones were capable of producing novel chemical entities, even when expressed in the heterogeneous host *E. coli* host that was not optimized for natural product expression. This study has not only characterized each of the compounds produced by anti-MRSA compound expressing clones, but there is clear evidence for a diversity of chemistry and cloned genome fragments among these 28 clones.

This study focuses on seven clones including P35B14, P22E10, P28I7, P37I0, P27M10, P6B5 and P5A4 that are involved in Cm modification. The supernatant from *E. coli* clone cultures contained multiple Cm derivatives, three of which are novel Cm derivatives. The mechanism by which these Cm derivatives are synthesized is believed to be by acylation of the Cm skeleton. This is supported by the genetic and biochemical data from these metagenomic

clones, indicating that a combination of metagenomic-encoded enzymes (i.e., acyltransferases) acted on the exogenously supplied Cm to produce these novel Cm derivatives. This "combinatorial metagenomics" method could be applied with other natural product scaffolds to generate novel derivatives of other chemical entities with enhanced or altered biological functions.

This study illustrates that each heterologous expressed metagenomic clone can contain a unique combination of genetic elements and biochemical products. Genetic characterization by subcloning of BAC DNA of clone P6B5 revealed the insert gene is *trfA*, with this single gene being necessary and sufficient for the antibacterial activity. The *trfA* gene product is known to be responsible for replication initiation and copy number control for RK2 plasmids (Perri et al. 1991); thus, having a copy of this gene in the metagenomic clone might be advantage for generating Cm derivatives. The TrfA ORF is highly conserved and encodes a putative single-stranded DNA binding protein (Ssb) that activates the origin of vegetative replication in diverse bacterial species (Wegrzyn et al. 2014). This single-stranded DNA binding property of TrfA might activate the expression of certain genes that are involved in modifying Cm for the production of variety of cm derivates. Out of seven clones that were involved in Cm modification, two of them (P6B5 and P35B14) contain *trfA* gene which was confirmed by sequencing. Sequence analysis from other five clones did not reveal the presence of *trfA* gene in their insets. This finding was not surprising since each BAC clone contains unique genetic elements; therefore, presence of similar gene in each clone is unlikely. Though all the seven clones were generating Cm derivatives but we found some variations in the production of Cm derivatives, these variations might be due to the presence of different gene(s) in each of this clone that regulate the generation of Cm derivatives. Further genetic characterization of these

clones need to be done to confirm the gene(s) that is responsible for generating biochemical compound.

A previous functional metagenomic study that identified Turbomycins A and B observed that these metabolites resulted from a combination of heterologous host chemistry (i.e., indole secreted by *E. coli*) with metagenomic clone-encoded chemistry (i.e., homogentisic acid pigment) resulting in novel natural products (Gillespie et al. 2002). Similar results were observed in this study that the metagenomic clone-derived chemistry acted on an exogenously supplied natural product scaffold, in this case Cm, resulting in novel Cm derivatives that had not been previously described. Given the toxicity associated with Cm that limits its clinical use, it would be of interest to evaluate the novel Cm derivatives discovered to see if they are similarly likely to induce any toxicity, or if they might have better potential for clinical application.

Chapter 5

Conclusion

Soil microbial communities are known to be a great resource for natural products but a majority of them have not been explored for their secondary metabolite synthesis because many of them are not readily cultured under laboratory conditions. In this study both culture-dependent and culture-independent approaches were used to discover antibiotics that inhibit the growth of methicillin-resistant clinical isolates of *Staphylococcus aureus* (MRSA).

Chapter 2. A novel cultivation approach using low-strength (1/200th) nutrient agar supplemented with soil extract and long incubation time was used for the isolation of soil bacteria that express antibacterial activity against MRSA. A collection of 548 unique bacterial and fungal isolates were isolated from soil using these novel cultivation techniques.Bacterial diversity analysis using 16S rRNA gene sequences of newly cultured isolates revealed that they represent diverse bacterial genera affiliated with the phyla *Acidobacteria, Actinobacteria, Bacteroidetes, Firmicutes,* and *Proteobacteria*. Two isolates, designated as A115 and F4, were found to inhibit the growth of pathogenic methicillin-resistant *Staphylococcus aureus* (MRSA). The isolate A115, member of the genus *Streptomyces,* produces a pink pigment after incubation for more than ten days. The isolate F4, identified as a *Nonomuraea* spp., produces a high molecular weight (>100kDa), heat stable reddish pigment associated with anti-MRSA activity. Genome sequencing using a combination of shotgun and mate-pair next-generation sequencing resulted in the complete assembled genome for each isolate, with the size of the A115 and F4 genomes at 8.6 Mb and 10.3 Mb, respectively. The %G+C contents of strains A115 and F4 were determined to be 71% and 70.4%, respectively. Phylogenetic analysis using multilocus sequence analysis with six housekeeping genes revealed that strain A115 was most closely related to

Streptomyces afghaniensis and *Streptomyces olindensis*; however, the low level of average nucleotide identity (ANI) values in comparing the A115 genome were 89.76% and 89.14% for *S. afghaniensis* and *S. olindensis*, respectively. These genomic results, combined with differentiation of strain A115 from other *Streptomyces* species by morphological and physiological characteristics, led to the conclusion that strain A115 represents a novel species of the genus *Streptomyces*, for which the name *Streptomyces alburnustigris* (Latin word for auburn tiger) sp. nov. is proposed. Phylogenetic analysis based on 16S rRNA gene sequence revealed that the closest phylogenetic relative of F4 strain was *Nonomuraea antimicrobica* YIM 61105. *In silico* analysis using anti-SMASH predicts that the A115 and F4 genomes encode many gene clusters for secondary metabolite biosynthesis, including the synthesis of terpene, aminoglycoside, thiopeptide, bacteriocin, oligosaccharide, phenazine, butyrolactone, siderophore, melanine and potentially other bioactive compounds produced by non-ribosomal peptide synthetase and polyketide synthetase pathways. Both *S. alburnustigris* A115 and *Nonomuraea* spp. strain F4 genomes are predicted to encode Type I, II, and III PKS pathways. The biochemical structure of the active anti-MRSA compounds are currently being characterized using liquid chromatography–mass spectrometry (LC/MS). An organic extract of A115 supernatant revealed strong activity against the fungal pathogens *Candida glabrata*, *C. krusei* and *Cryptococcus neoformans*. The antifungal compounds extracted from A115 supernatant appeared to be novel; however, none of the organic extracts were found to be active against MRSA and the compound(s) active against MRSA will require alternative extraction methods for their biochemical structural elucidation. This study identified novel bacterial isolates with anti-MRSA activity and demonstrates the utility of novel cultivation techniques in obtaining

previously uncultured and phylogenetically diverse soil microorganisms, some of which express potent bioactive secondary metabolites.

Chapter 3. In this study, a collection of bacterial rhizosphere isolates were screened to identify novel chemical compounds for MRSA control. Five *Bacillus* strains that expressed metabolites with anti-MRSA activity were identified. Among them, *Bacillus amyloliquefaciens* strain AP183 was found to produce a novel macrodiolide compound described herein as Bacillusin A that has potent anti-MRSA activity with a minimum inhibitory concentration of 0.6 µg/mL. Because Bacillusin A has a short half-life after extraction, we hypothesized that it may not persist within living tissue and would therefore be suitable for *in vivo* application. AP183 was tested *in vivo* as a skin probiotic to prevent MRSA infection using a mouse model. Mice were simultaneously challenged with bioluminescent *S. aureus* strain Xen29 with and without AP183 spores in two separate wounds. In additional experiments, we tested the effects of AP183 spores with and without accompanying secondary metabolites. After challenge, skin wound healing was monitored for one week and *S. aureus* growth was assessed by bioluminescent imaging. After one week, mice were sacrificed and wounds were homogenized and plated to determine culturable bacterial counts and to conduct a culture-independent skin microbiome analysis. Our *in vivo* studies showed that co-administration of secondary metabolites and AP183 spores resulted in a significant reduction in the number of *S. aureus* colonization compared to a negative control. Molecular phylogenetic analysis revealed a significant reduction in *S. aureus* relative abundance when AP183 was applied while the relative abundance of other bacterial taxa increased in the skin microbiome as a result of probiotic administration. In future work, the *in vivo* efficacy and safety for the application of strain AP183 and its active metabolites will be determined.

Chapter 4. A metagenomics approach was also applied in this study in order to discover antibacterial compounds. A metagenomic library was constructed using high molecular weight DNA from the microbial assemblage from the Cullars Rotation agricultural soil (a plot without N or P amendments) and cloned that DNA into a shuttle bacterial artificial chromosome (BAC) vector. The soil metagenomic library is comprised of 19,200 *E. coli* clones with an average insert size of 110 kb. *E. coli* clones containing metagenomic DNA were screened for inhibition of growth of MRSA using a 96-well microtitre plate format. *In situ* lysis of the *E. coli* host enabled detection of both intra- and extracellular compounds, yielding a total of 28 anti-MRSA clones. Transformation of naïve *E. coli* with BAC DNA isolated from anti-MRSA clones confirmed the presence of their anti-MRSA activity. Sequencing and sub-cloning of these clones revealed genes predicted to be involved in various biosynthetic pathways as well as many genes with unknown functions. This culture-independent approach discovered seven metagenomic clones with the capacity to modify chloramphenicol which was added to the *E. coli* culture medium, thereby resulting in modification of an existing antimicrobial scaffold. LC-MS analysis of the organic extract of the clones revealed three new chloramphenicol derivatives. Chemically synthesized chloramphenicol derivatives tested showed antibacterial activity against MRSA, *Mycobacterium intracellulare* and *M. tuberculosis* with MICs of 27.6, 12.5 and 50.0 μg/mL, respectively. These results demonstrate that large-insert soil metagenomic libraries can be screened using innovative functional screening methods to access previously undescribed genomic and biochemical diversity.The progress made in these studies toward generation of large-insert metagenomic libraries in shuttle BAC vectors will be applied in future for generation of larger-scale libraries that can encompass a greater diversity of soil microbial metagenomes and be expressed in multiple hosts. In particular, the use of specific *E. coli* and other

heterologous hosts engineered for expression of polyketide synthases as well as other biosynthetic pathways will take further advantage of these libraries for natural product discovery.
