Abstract

The Wetumpka impact structure is an approximately 5 km diameter crater that resulted from a shallow marine cosmic impact in the northeastern Gulf of Mexico during Late Cretaceous (latest Santonian to earliest Campanian). Presently, this impact structure is a surficially exposed feature with a broad, arcuate crystalline rim, an interior sedimentary and polymict breccia unit, and an extra-crater terrain consisting of horst and graben structures. Recent scientific core drilling within the crater-filling breccias has shown that the uppermost impact stratigraphy is well preserved. Two of those drill cores, 09-03 and 09-04, were studied by conventional lithologic logging methods and in part by using X-ray computed tomography (CT) scans in order to describe the sedimentological characteristics, specifically the Lithofacies belonging to constituent resurge and rim-collapse sediments. Qualitative results from the resurge interval of core 09-03 indicate a northerly directed debris flow occurred first, then the resurge arrived, and finally a southerly or seaward-directed, more aqueous anti-resurge occurred. Proximal field and drill core structural relationships were used to infer the preservation state of the resurge deposits, which accumulated in downthrown blocks within the crater. Lithofacies patterns and grain-size trends confirm that the core 09-04 penetrates a slumped remnant of the southern overturned flap. Lithofacies and stratigraphic patterns below the overturned flap in core 09-04 suggest that underlying impactite sands are also an interval of sheared and partially disaggregated sedimentary flap material.

Acknowledgments

Scientific drilling within the Wetumpka impact structure would not have been possible without the NASA PGG grant #NNX09AD90G awarded to David King and Jens Ormö. Further financial aid was provided by American Association of Petroleum Geologists Fred A. and Jean C. Dix Named Grant and Gulf Coast Association of Geological Societies grants-in-aid.

This author would like to thank the guidance and insight from Dr. David King and committee members Ashraf Uddin and Mark Steltenpohl. Jens Ormö and Scott Harris also provided informative discussion and insight.

This author would like to thank the patience and inspiration provided by my wife, Debbie Wilson, and my son, Nathaniel Markin. They were a guiding light through a long and dark tunnel. We made it together.

Introduction

Impact cratering is among the most dominant geological processes within the solar system. Although the evidence of impacts can be disguised on terrestrial bodies such as Venus, Earth, Europa, Io, and Titan by various geological processes (i.e., volcanism, erosion, and tectonics), in the instance of Earth in particular, impact cratering has emerged as an increasingly important constituent of Earth's geological history. Beginning with studies such as Shoemaker (1960) at Barringer Crater, Arizona, terrestrial craters have experienced a near exponential rate of discovery with a current rate of ~2-3 craters per year (Grieve, et al. 1995; Stewart, 2011). Moreover, aside from 131 recognized, Phanerozoic craters greater than 1 km in diameter, conservative statistical analysis by Stewart (2011) predicts that 714 impact craters >1km diameter with a subset of 228 impact craters >2.5 km diameter remain to be found for the Phanerozoic. However, although scientific techniques and procedures for discovering impact craters have become increasingly refined (i.e., French, 1998; Stewart, 2003; French and Koeberl, 2009), the understanding of the specific impact processes that control crater morphology, shock metamorphism and melting, and impact stratigraphy are aggressively evolving. Further, although the basic stages of impact cratering processes are well understood (i.e., contact/compression, excavation, and modification stages in Melosh, 1989, and French, 1998), there is a component that drastically complicates crater formation and, in particular, modification stage evolution: water.

Marine impact craters involve an upper layer of water within the target stratigraphy, the strata impacted, deformed, and disrupted by an impacting bolide. Even though marine impact craters are currently recognized among the minority of known impact craters, listed as 20 craters in Goto (2008), marine impact craters should be, if not a majority, a significant proportion of impact craters on Earth. Because of the dominance of oceanic cover on the earth's surface and the greater preservation potential of active basins, marine impact craters should be the dominant type of impact on earth. Thus, marine impact craters have become an area of increasing academic interest and relevance within impact geology and the geosciences. Moreover, impact craters such as Avak, Alaska; Ames, Oklahoma; and Redwing, North Dakota are proven hydrocarbon reservoirs demonstrating a general commercial success rate of ~50% within petroliferous basins (Kirshner and Grantz, 1992; Donofrio, 1998), and larger impact craters such as Chicxulub can induce hydrocarbon maturation within depths typically too shallow for conventional hydrocarbon generation (Grieve and Therriault, 2000). Therefore, there is a fundamental academic and economic need for further scientific research of impact processes and their resulting stratigraphy.

The Wetumpka marine impact structure of Wetumpka, Alabama, located in Elmore County, is an exceptionally-preserved, ~ 6-km diameter, shallow-marine target impact crater, which formed during Late Cretaceous (i.e., late Santonian to earliest Campanian). This impact formed within a mixed target environment of unconsolidated to poorly consolidated Cretaceous sediments and underlying schist and gneiss of pre-Mesozoic crystalline basement. Originally recognized and studied as an astrobleme by Neathery et al. (1976), Wetumpka became the only confirmed impact crater of the eastern Gulf Coastal Plain following the discovery of shocked minerals and elevated siderophile elemental composition (i.e. iridium, nickel, and cobalt) as

reported by King et al. (2002). Unlike many other deeply-buried, marine impact craters (i.e., Chesapeake Bay, Mjølnir, Ames, and Avak, among others), the Wetumpka impact structure has allowed direct observation through outcrop studies and mapping (i.e., Neathery, 1976; Nelson, 2000), and cost-effective shallow drilling, and limited geophysical investigation. Furthermore, following the serendipitous exhumation of the Wetumpka impact structure from its post-Upper Cretaceous impact cover, possibly during Quaternary (see Neathery et al., 1976), much of the original impact stratigraphy remains including the uppermost resurge impact facies (Ormö et al., 2010; King et al., 2010). Shallow drilling and preliminary analysis conducted by King et al. (2010) and Ormo et al. (2010) along with sedimentological and stratigraphic data of this study will assist investigation of how the shallow target marine depth affects the impact processes of mostly unconsolidated mixed-siliclastic targets.

Objectives

During the summer of 2009, four shallow drill-cores were obtained to study the shallow subsurface stratigraphy of the north-western crystalline rim (Gardner #1, 09-01), central polymict breccia (Buck Ridge Road #1, 09-02), chalk meadows (Bailiff #1, 09-03), and southeastern rim (Wadsworth #1, 09-04). Figure 1 shows the location of these four wells. Following preliminary studies presented by King et al. (2010) and Ormö et al. (2010), wells 09-03 and 09-04 were chosen for further detailed study of the catastrophic sedimentation of the interior crater-filling breccias and sediments of rim collapse (mega-slumping facies) and violent return of the impact-excavated sea (resurge facies). Using the principles of facies analysis discussed by Miall (1999), these drill-cores along with the existing body of work at Wetumpka are referenced to pursue the following objectives:

1. To provide a digital documentation of these drill cores for this project and for the benefit of future workers on the Wetumpka impact structure;
2. To provide detailed, non-interpretive, descriptive data of sedimentological, stratigraphic, and structural parameters for the purposes of this project and future studies;
3. To investigate the sedimentary and stratigraphic characteristics and lithostratigraphic patterns of the resurge and mega-slumping facies;
4. To help elucidate the timing, mode of deposition, and sequence of events following the impact, particularly the resurge and mega-slump facies of this impact structure;
5. To contribute to a growing scientific body of work on shallow marine impacts, as a contribution toward future studies of other shallow marine-impact structures.

Geologic Setting and Crater Morphology

The Wetumpka impact structure is a five-kilometer diameter crater located in Elmore County, central Alabama (Figure 1). Wetumpka has a deep inner crater, a broad horseshoe-shaped, northern crystalline rim, and an extra-crater terrain of structural deformation to the south (King et al., 2002). Because the Wetumpka structure is interpreted to be a shallow marine impact, the extra-crater structural terrain (EST) to the south is interpreted to be an *in situ* collapse feature of horsts and grabens (King et al., 2006). This extra-crater structure (EST in Figure 1) was likely the consequence of gravity-driven movement in wet, unconsolidated, and unstable target materials, and the violent resurge of sea water. Extra-crater deformation extends out 7.6 km from crater center towards the south. Within the shallow subsurface, the inner crater is filled with an upper impact stratigraphy of reworked ejecta and slumped megablocks (King, et al., 2006). The crystalline rim (CR) ranges from an intact, steeply-dipping schist-gneiss to weathered crystalline ejecta within a sandy, impactite matrix.

Figure 1. Geologic map of the Wetumpka impact structure. Crater morphology is labeled. Scale bar = 1km. Striped yellow in crystalline rim is crystalline ejecta (D. T. King, Jr., personal communication, 2010). Wells, 09-03 and 09-04, are labeled. Transect (A-A') for Figure 2. Insert: physiographic map of Alabama, from King et al. (2002). Geologic map modified from Johnson (2007). Wells marked 1-98 and 2-98 are the same as 98-01 and 98-02, respectively.

The Wetumpka impact crater lies in crystalline and Upper Cretaceous target stratigraphy, in stratigraphic order, pre-Mesozoic metamorphic basement, poorly-consolidated sediments of the Tuscaloosa Group, Eutaw Formation, and lower Mooreville Chalk of the eastern Gulf Coastal Plain. Previously, water depth was estimated to be 35 to 100 meters. Following results from Ormö et al. (2010), recently identified resurge deposits are interpreted to indicate very shallow marine depth at time of impact. Based on the youngest target sediments, the Wetumpka impact is thought to have occurred ~ 83.5 m.y. ago in the lower transgressive systems tract of the lowermost Mooreville Chalk (King et al., 2007; King and Petruny, 2010). A recent absolute date of 84.4 +/- 1.4 m.y. (Wartho et al., 2011) generally agrees with previous estimates of age, and crater age and target strata are discussed in depth in the section Target Stratigraphy.

Previous Work

The Wetumpka impact crater has been recognized as an anomalous structure for well over 100 years; however, the structure had not been proposed as impact in origin until work by Thornton L. Neathery, Robert D. Bentley, and Gregory C. Lines (Neathery et al., 1976). Further mapping and extensive outcrop studies by Nelson (2000) recognized crater-filling breccia and rim structures consistent with impact craters. Utilizing two wells that penetrated the central polymict breccia, subsequent work and confirmation of impact origin were achieved by King et al. (2002; 2003). Confirmation was achieved with the discovery of shock-characteristic angles within plane sets of planar deformation features (PDF), and elevated levels of some key siderophile elements of iridium, cobalt, nickel and chromium, contained within a impactite polymict breccia.

Currently, geophysical investigation at the Wetumpka impact structure has been limited. Prior to the scientific drilling of 98-01, 98-02, 09-01, 09-02, 09-03, and 09-04 wells, Wolf et al.

(1997) interpreted a gravity survey transect as having residual gravity of a negative gravity feature with a possible central peak. Relative negative gravity features are characteristic of impact structures. Utilizing the gravity data of Wolf et al. (1997) adjusted for regional trends, a subsequent gravity model by Robbins et al. (2011) shows a central peak and a thicker sedimentary breccia to the east. This model is in best agreement with field gravity measurements (Figure 2).

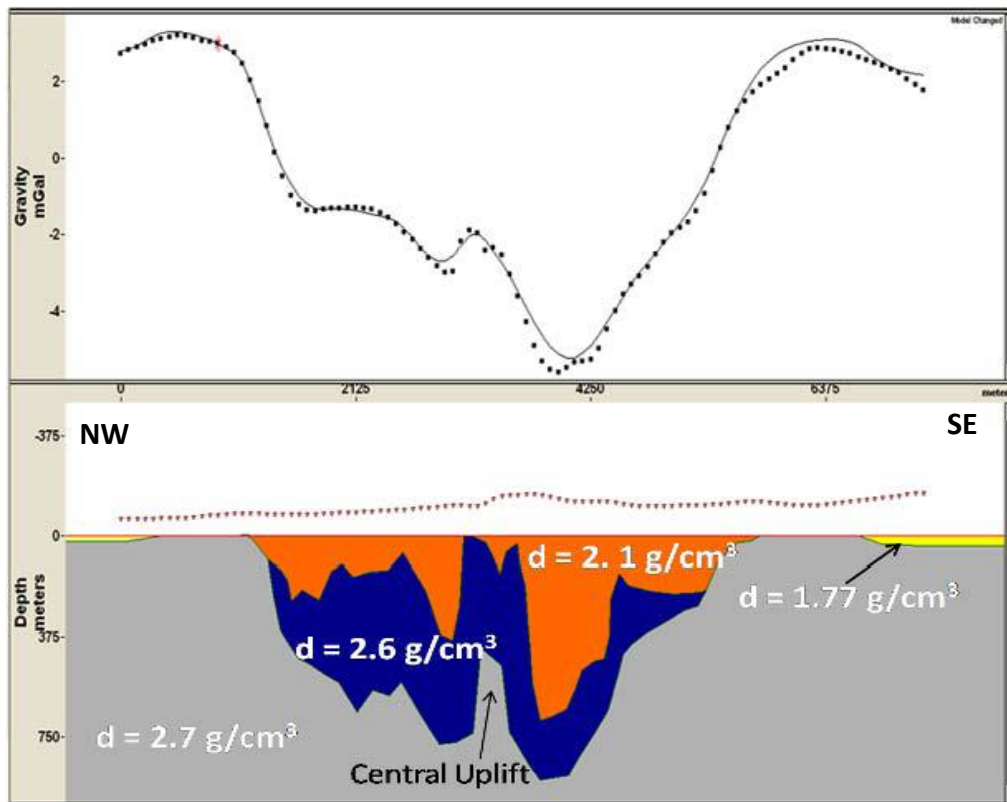

Figure 2. Gravity model for Wetumpka impact structure. Transect is west to east (see Figure 1 for approximate transect line). From Robbins et al. (2011).

Subsequent of mapping and confirmation of Wetumpka's impact origin, scientific investigation has focused upon the genetic origin and subsurface character of the Wetumpka impact stratigraphy. Following work by King et al. (2002; 2003) and Johnson (2007), shallow subsurface drill-cores 98-01 and 98-02 show an intercalated stratigraphy of sedimentary

megabreccia (SB) and polymict megabreccia containing crystalline and Upper Cretaceous clasts. Polymict megabreccia (PB) is a mixed, sedimentary and crystalline breccia within an impactite sand matrix. King et al. (2006) interpreted a significant role for water with crater formation. Because the veneer of coastal plain stratigraphy significantly thins to the north, King et al. (2006) proposed that the resulting rim was heterolithic in composition. Thus, the saturated and mostly unconsolidated southern rim would collapse almost immediately following collapse of the transient crater whereas the northern crystalline rim remained stable and resistant to collapse. Furthermore, King et al. (2006) interpreted that the return of excavated sea water (resurge) would further exasperate the collapse of the southern rim. Due to a tentative, interpreted trajectory of impact from the southwest, King et al. (2006) suggest a much stronger southern resurge; this is based on computer simulations of marine impact craters that show increased resurge strength in an up-range direction (Shuvalov et al., 2005). King and Petruny (2009) reported melted dinoflagelates within “chalk meadows” in the interior which suggested that they were remobilized post-contact stage sediments.

Finally, current work within the Wetumpka impact crater was made possible by a NASA grant awarded to David King and Jens Ormö for the previously mentioned four new drill cores. The wells, 09-01, 09-02, 09-03, and 09-04 were drilled to depths of 88, 23.5, 90, and 218 m, respectively. Preliminary interpretations by King et al. (2010), propose that 09-01 contains an overturned crystalline flap, 9-02 has an interval of polymict breccia with both sedimentary and metamorphic blocks, 9-03 contains a resurge of distal ejecta and ripped-up sediments in the upper portion of the well, and 9-04 contains a preserved slumped, overturned assemblage of Upper Cretaceous units, which are interpreted to be an overturned flap due to reversed stratigraphy. Furthermore, analysis of matrix material and utilization of a line-log technique for

granulometric analysis in the upper part of drill core 09-03 (Ormö et al., 2010) suggests that the uppermost resurge deposit within this well is “sediment laden” and suggestive that the Wetumpka impact structure is shallower than previously believed. Subsequent work, discussed in detail in this text, used X-ray computed tomography (X-ray CT) to differentiate sedimentological structures and lithostratigraphic units within the resurge of 09-03 that were generally consistent with a mud-flow interpretation (Markin et al., 2010).

TARGET STRATIGRAPHY

Unlike many surficial, conventional geological processes, impact cratering does not contribute significant, additional material to existing stratigraphy. Instead, impact cratering superimposes unique processes of shock metamorphic, igneous (melting), sedimentary (i.e., resurge), and deformational processes upon pre-existing, target stratigraphy. Consequently, the complex structural and stratigraphic result of impacting is challenging to understand. However, with greater resolution of pre-existing, vertical and lateral stratigraphy, the seemingly random result is increasingly easier to understand. For example, with proper identification of original stratigraphic position, properly-identified constituents allow the identification of overturned flap, ejecta patterns, timing of emplacement and other inherited stratigraphic patterns possibly hidden within brecciated stratigraphy. Therefore, the following chapter discusses the target stratigraphy in depth for proper identification of original stratigraphic source to help assist analysis of sediment provenance and crater evolution.

Figure 3. Stratigraphic column for target stratigraphy. Pre-K = Emuckfaw group with intrusive Kowaliga-Zana Gneiss. Maximum and minimum water depths are indicated by different shades of blue (Modified from King, 1997).

Crystalline Basement: Kowaliga-Zana Gneiss and Emuckfaw Group

Within the confines of this study, with the exception of questionable, highly-saprolitized crystalline breccia near the base of well 09-04 of King et al. (2010), occurrences of intact-crystalline breccia were not encountered within field studies or drill-core. Nevertheless, within impactite breccia matrix, a disaggregated, mineralogical admixture is noted from this study that likely involves the crystalline basement. Therefore, it is important to acknowledge the general lithological and mineralogical composition of the crystalline basement that could become present within the finer-grained matrix of the slurry and fallback breccia facies of the Wetumpka impact crater.

Emuckfaw Group. Generally, Emuckfaw Group is reported by Raymond et al. (1988) to be a diverse, metasedimentary sequence of medium-grained muscovite-biotite-quartz-feldspar gneiss, fine-grained graphite-garnet-muscovite schist, graphite-garnet-muscovite schist, and quartzite along with locally occurring thin amphibolites and aluminous graphitic schists. Raymond et al. (1988) also mention rare ultramafic pods; however, previous workers have not at this time observed these within the Wetumpka area. From Emuckfaw Group exposures of the crystalline rim, Neathery et al. (1976) observed a consistent lithology of biotite-garnet-feldspathic schist throughout the crystalline rim, exposures of meta-orthoquartzites and aluminous, graphitic schists in the western rim, and locally, a thin amphibolite in the eastern portion of the crystalline rim (near well 09-04). Within predominate schists of the crystalline rim, Nelson (2000) also observed significant muscovite and plagioclase content that ranging from 0 to 15 percent of the total volume; these schists are observed to locally grade towards quartzites. Furthermore, Nelson (2000) also observed reddish-purple, euhedral to subhedral garnets (almadine?), which were up to 4 mm in diameter and associated with both micaceous and

quartzose schists with tourmaline present with graphitic schists and possibly decreasing garnet content with increasing graphitic content.

Therefore, based upon previous work, mineralogical input from the Emuckfaw Group into impactite breccia matrix beyond ubiquitous quartz would be muscovite, biotite, plagioclase, graphite, euhedral-subhedral garnets, unknown amphibole species, and tourmaline. Due to the meta-sedimentary (meta-greywacke) nature of the Emuckfaw Group, potassium feldspar and zircons would be anticipated additions as well.

Kowaliga-Zana Gneiss. Intruded into the Emuckfaw Group, the Kowaliga and Zana Gneiss are, respectively, a gray, coarse-grained feldspathic augen gneiss and gneissic quartz monzonite-granite which are strongly lineated and have increasing foliation near margins (Raymond et al. 1988; Drummond et al., 1997). Derived from I-type parent magma of felsic to intermediate composition along with likely meta-sedimentary contamination, the Kowaliga-Zana gneiss is thought to be emplaced during the 460-Ma Taconic Orogeny (Russell et al., 1987; Drummond et al., 1997).

Specifically, for the Wetumpka crater, Nelson (2000) observed biotite-rich, muscovite-poor outcrops of micaceous, K-Feldspar augen gneiss (Kowaliga Gneiss) which include quartz and both potassium feldspar and myrmekitic plagioclase in the northeast portion of the rim. Also, north and proximal to the Wetumpka crater rim, Nelson (2000) observed occurrences of Emuckfaw Group and Kowaliga Gneiss within stream channels with Kowaliga Gneiss exhibiting potassium feldspar augens, biotite and high quartz content. Other studies that have included the Kowaliga Gneiss outside of the immediate area of Wetumpka have observed mineralogical composition of quartz, potassium feldspar and plagioclase porphyroblast, biotite, muscovite, chlorite and accessory minerals of sphene, apatite, zircon, and epidote, in the Lake Martin area,

northeast Elmore County (Sterling, 2006); In addition, within eastern Elmore County near Tallahassee, Kowaliga Gneiss is observed, along with common, previously mentioned mineralogical constituents, epidote and microcline augens with tartan twinning and fine-grained biotite, muscovite and quartz inclusions. Therefore, the anticipated, potential disaggregated crystalline basement input within impact breccia matrix is primarily subhedral quartz, principally potassium feldspar (microcline and orthoclase) and lesser amounts of plagioclase feldspar, micas of principally biotite with subordinate muscovite and chlorite, and accessory minerals of epidote, apatite, zircon, and sphene.

Eastern Gulf Coast Plain: Tuscaloosa Group and Eutaw Formation

Following the breakup of Pangaea and initial formation of the Gulf of Mexico during Late Triassic to Early Jurassic, the volcanic rifted-margin on North America's southeastern margin transitioned to the passive margin wedge of the Eastern Gulf Coastal Plain (Salvador, 1987; Mancini et al., 2008). Although substantial sedimentary deposition of Upper Triassic through Lower Cretaceous strata occurred deeper within the sub-surface of the Gulf of Mexico (Mancini et al., 2008), within the arcuate post-Paleozoic outcrop belt of the Eastern Gulf Coastal Plain, only Upper Cretaceous sediments of the Tuscaloosa Group and Eutaw Formation exist within the target stratigraphy of the Wetumpka impact crater (Neathery et al., 1976; King et al., 2006). Within the Alabama Upper Cretaceous outcrop belt, stratigraphic architecture of relevant Upper Cretaceous formations transition from the eustatic-tectonic derived stratigraphy of the eastern margin of the Mississippi Embayment to the largely eustatically derived Upper Cretaceous sediments of eastern Alabama and western Georgia. Upper Cretaceous sediments of Central Alabama lie within a zone of transition between these two fundamental areas that have received lesser scientific scrutiny than neighboring eastern and western Alabama Cretaceous

stratigraphy. Upper Cretaceous stratigraphy of central Alabama could include stratigraphic and sedimentological character similar to both western and eastern Alabama Upper Cretaceous stratigraphy and intraformational facies (D. T. King, Jr., personal communication, 2010).

Following the formation of the Mississippi Embayment, limited tectonic influence upon post-Tuscaloosa, Cretaceous stratigraphy is possible due to volcanism (Baksi, 1999), halokinesis, and thermal subsidence (Cox and Van Arsdale, 2002; Mancini et al. 2008). However, global sea level curves and eustasy are attributed to be the principal influence on transgressive and regressive cycles of the Eastern Gulf Coastal Plain (King, 1994; Mancini et al. 2008).

Tuscaloosa Group. The Tuscaloosa Group ranges from a fluvial-deltaic and marginal marine complex within western Alabama to a poorly-sorted, feldspathic, predominately fluvial sedimentary deposit of the undifferentiated Tuscaloosa Formation of eastern Alabama (Mancini et al. 1987). Consisting of the lower Coker Formation and the upper Gordo Formation within the up-dip (outcrop) in Alabama, the Coker Formation is generally described as a fine to medium grained, micaceous, cross-bedded sand and variegated, micaceous clays with subordinate, thin gravel beds whereas the Gordo Formation consists of a lower, predominately gravelly sand and a cross-bedded, locally gravelly sand in the upper part with interbedded, gray, moderate-red, red-purple, and mottled clays (Raymond et al., 1988). Respectively, thicknesses for the Coker and Gordo formations are estimated to be 70 to 152 and 35 to 91 meters in outcrop for a combined 105 to 243 meters (Raymond et al. 1988). However, in the vicinity of the Wetumpka impact structure, thicknesses are estimated to be 60 meters for the Tuscaloosa Group (Neathery et al., 1976; King et al., 2003). In addition, the Tuscaloosa is thought to be middle Cenomanian to Turonian in age (Mancini et al. 2008). However, Johnson (2007) reports palynological data that

suggest an age in the range of late Albian to Cenomanian, which was obtained from Tuscaloosa paleosols within a semi-intact sedimentary block drilled in well 98-01.

Although predominantly terrestrial in origin, the Tuscaloosa Group contains marginal marine sediments in western Alabama within the basal Eoline Member of the Coker Formation, which consist of very fine to medium grained, thinly laminated, and finely glauconitic sand and silt, along with dark-grey, carbonaceous clays (Drennen, 1953; Raymond et al., 1988). Another marine incursion can be found near the top of the Coker Formation corresponding with the maximum flooding surface identified by Mancini et al. (2008) within subsurface logs and outcrops within Western Alabama. This latest Tuscaloosa marine incursion likely transgressed as far as western Middle Tennessee, where it is identified as intercalated upper shoreface sands (Marcher and Stearns, 1962). Marcher and Stearns (1962) interpreted a “Tuscaloosa Sea,” which was likely a narrow inlet that flanked the eroding, uplifted Paleozoic highlands of the Mississippi Embayment (see Cox and Van Arsdale, 2002). Although glauconitic, marine sediments are found with southeastern Elmore County (Szabo et al. 1988), Drennen (1952) states that there are no known marine Tuscaloosa sediments east of the Coosa River nor has recent, substantial field mapping or outcrop studies (e.g., Neathery et al., 1976; Nelson 2000; King and Ormö, 2007) revealed any Tuscaloosa sediments of marine or marginal marine origin.

Fundamentally, the terrestrial facies of the Tuscaloosa Group include (1) floodplain facies of overbank/paleosol deposits of oxidized, red-maroon-purple, heavily bioturbated, silty clays interbedded locally with olive-gray crevasse splay sands and, in one locality, high concentrations of biotite (Reinhardt et al., 1986), and (2) stacked or amalgamated 3- to 6-meter thick, fining upward, mud or quartzite conglomerates overlain by trough cross-bedded channel sands (Reinhardt et al., 1986; Savrda et al., 2000). In a few places, oxbow lacustrine deposits of

laminated, fossiliferous (leaf-rich), grey clays have been found (Smith, 1984; Savrda et al., 2000). Within eastern Alabama, these Tuscaloosa alluvial facies are interpreted to be part of a complex stratigraphic architecture derived from a hybrid form of tropical, high discharge, anastomosing alluvial fans and braided-rivers of moderate slope (King, 1997), which locally resemble more typical meandering fluvial systems (Reinhardt et al., 1986).

Sedimentologically, white, buff, red, and purple channel sands of fining-upward cross-bedded sequences are well-defined planar to trough cross-bedded sands with basal, reworked flood-plain clasts or quartzite granules, pebbles and cobble conglomerates that are coarser near the base of the Gordo (Drennen, 1952; Reinhardt et al., 1986; Savrda et al., 2000). These channel complexes fine upwards into oxidized overbank/paleosol facies that are pervasively bioturbated with dense, interpenetrating *Taenidium* (Savrda et al., 2000), an ichnofossil of meniscate-backfilled, and straight to sinuous burrows likely formed by insect activity.

Lithologically, discrete, pristine planar and trough cross-bedding of micaceous, immature arkosic sands absent of any bioturbation along with heavily bioturbated (*Taenidium*-bearing), red and purple, paleosol/overbank silts and clays are diagnostic of Tuscaloosa Group sediments. In addition, overly gravelly sands and coarser conglomerates likely belong to the Gordo Formation.

In addition to lithological and stratigraphic composition, Tuscaloosa Group mineralogy can be arkosic and quartzose (Nelson, 2000) and can contain some heavy minerals. Sayers and Uddin (2010) have reported detrital heavy minerals of garnet, zircon, tourmaline, rutile and opaques from a 0.19 to 0.85 percent fraction from localities of chemically-weathered Tuscaloosa Formation in eastern Alabama and western Georgia in close proximity to piedmont sources. In the previously mentioned marginal marine facies (specifically beach placer deposits) of the Tuscaloosa in middle Tennessee (Marcher and Stearns, 1962), accessory minerals include

tourmaline, epidote, zircon, titanite, kyanite, staurolite, leucoxene, monazite, topaz, tremolite, ilmenite, limonite and apatite. Therefore, within a disaggregated Tuscaloosa-derived impactite-breccia matrix, Tuscaloosa could input minor amounts of these minerals along with rare biotites. Obviously, sourced from an alluvial and oxidized environment, these accessory minerals are likely to be heavily chemically and physically weathered.

Eutaw Formation. In contrast to the Tuscaloosa Group, the Santonian to early Campanian Eutaw Formation is a heterolithic, marine to marginal marine formation consisting of a lower, unnamed member of non-calcareous, glauconitic, cross-bedded to massive, locally fossiliferous, fine to medium-grained sands with interbedded, laminated silts and clays (Raymond et al., 1988), which are disconformably incised into underlying Tuscaloosa Group sediments (King, 1990). However, the upper member of the Eutaw Formation, the Tombigbee Sand Member is disconformable with the underlying member and is non-calcareous to calcite-cemented, fossiliferous, glauconitic, fining-upward, fine sand to silty clay that is mostly conformable and gradational with overlying Mooreville Chalk (Raymond et al., 1988; Mancini et al., 1994). Both the lower unnamed member and Tombigbee Sand Member thin from western Alabama to the east and thicken from offshore-subsurface to up-dip outcrop with a maximum thickness of 170 meters to the west and thinning to 38 meters in the east (Raymond et al., 1988; Liu, 2007). Within the Wetumpka area where the Eutaw Formation begins to thin substantially, the thicknesses are estimated to be 30 meters (Neathery et al., 1976). Furthermore, the Tombigbee Sand thicknesses can range from 1.5 to 6 meters, absent in eastern Alabama, and is discontinuous within western to central Alabama (Raymond et al., 1988).

Although heterolithic, stratigraphic patterns have been recognized by Mancini et al. (2008) among others that show fining-upward sequences with general back-stepping facies

associations as part of a transgressive systems tract and, possibly, the uppermost low-stand systems tract (C. E. Savrda, personal communication, 2009). The lower, unnamed Eutaw member is generally dominated by paralic marine sand facies comprising linear barrier-island, inner shelf deposits of linear submarine sand bars, turbiditic sands, and tempestites, and back-barrier deposits of lagoonal, carbonaceous silts and clays, and tidal deltas. A subordinate facies assemblage of estuarine incised valley-fill is recognized and well-studied within the eastern Alabama and western Georgia coincident with the modern Chattahoochee River valley. This assemblage of facies resulting from tidally-influenced environments of deposition include bay-head deltas, bay muds of fair-weather and storm conditions, and tidal channels and shoals (Frazier and Taylor, 1980; Savrda and Nanson, 2003; Bingham et al., 2008). Where lower shoreface and inner shelf environment of deposition transgressed to the position of the modern outcrop belt, outcrops of the Tombigbee Sand Member are the result (Mancini and Soens, 1994).

For the Eutaw Formation within the Wetumpka region, Frazier and Taylor (1980) describe a basal, bioturbated, gravelly-sand overlain with cross-bedded fine sand and mud drapes along with rare intercalated fossiliferous muds that contain bivalve fragments and lignitized wood fragments. Moreover, Nelson (2000) has identified predominant *Ophiomorpha nodosa* within Eutaw outcrops, located both within and outside the impact crater. Likewise, in some previous reports, Frazier and Taylor (1980) and Mancini and Soens (1994) reported *Ophiomorpha nodosa* dominance in fully bioturbated to moderately bioturbated sands and muds in the unnamed lower member of the Eutaw. However, within tidal inlet/tidal delta facies of the upper lower Eutaw, Savrda et al. (1998) reported more diverse assemblages of ichnofossils including *Macaronichnus*, *Conichnus*, *Skolithos*, *Dactyloidites*, and comparatively rare *Ophiomorpha* with good preservation of herringbone cross-stratification. Furthermore, within

incised-valley-fill facies and the estuarine bay muds and sands, muds and sands have a bioturbated, homogeneous fabric where discrete ichnofossils are identified such as *Planolites*, *Terebellina*, and *Teichichnus* (also some *Ophiomorpha*, but only with tempestites). Also, within these estuarine settings, large lignitized wood fragments and laminated or bedded lignite have been observed (Frazier and Taylor, 1980; Savrda and Nanson, 2003).

Interpreted as offshore transition to lower shoreface, Mancini and Soens (1994) identify three fundamental lithofacies within the Tombigbee Sand. However, the lowermost lithofacies is essentially identical to the uppermost unnamed member, a cross-stratified, glauconitic, non-calcareous, fine to medium sand, distinguishable only with an interceding transgressive lag. On the other hand, Mancini and Soens (1994) state that the upper two members have varying calcite cementation with bioturbated, massive fabrics in which cementation can encompass entire beds (Savrda and King, 1993) or discontinuous concretions (Savrda and King, 1993; Mancini and Soens, 1994; Liu, 2007). Moreover, the diachronous overlying Mooreville Chalk and underlying Tombigbee contact can be gradational towards sandy-silty marl or sharp as a calcareous, bored sandstone-hardground surface termed herein as the “Tombigbee caprock.” Liu (2007), in contrast, picks the contact where calcareous clay (marl) exceeds the sand volume. Within the Wetumpka area, Nelson (2000) observed few recognizable Tombigbee sand outcrops occurrences. Within the Wetumpka area, Tombigbee Sand intervals are not known to exceed one meter and resemble the “Tombigbee caprock” of Savrda and King (1993). Following this precedent, only indurated, calcareous sandstones are interpreted as Tombigbee Sand Member.

Lowermost Mooreville Chalk (uppermost target sediment). Utilizing (U-Th)/He geochronological methods on apatite and zircon samples, an absolute, a radiometric age of 84.4 ± 1.4 Ma was obtained by Wartho et al. (2011) which is in general agreement with the

biostratigraphic estimate of ~83.5 million years by King et al. (2007). However, with the biostratigraphic, lithostratigraphic, and sequence stratigraphic framework of Liu (2007), the Wetumpka impact event likely has occurred during a later time than the absolute age based on comparisons with semi-intact strata of lowermost Mooreville chalk at Jasmine Hill Road in the extra-crater structural terrain, described by Nelson (2000). Within the resurge interval of 09-03, semi-intact chalk clasts are entrained within the resurge, thus, at least one chalky horizon must exist in target stratigraphy. Moreover, Ormö et al. (2010) suggested that water depth was likely closer to the minimum value proposed. Thus, impact is interpreted to have occurred during a regressive phase (marl or clayey deposition). With the Jasmine Hill outcrops and drill-core data (detailed in results and discussion), a probable age of approximately 83.9 million years is estimated. Constrained by the radiometric age and its limits of uncertainty, the Wetumpka impact must have occurred during the deposition of the lowermost Mooreville Chalk. Interpreted chronostratigraphic and lithostratigraphic position along with absolute dates of Wartho et al. (2011) are presented in Figure 4.

Figure 4. Chronostratigraphy and lithostratigraphy of the Wetumpka impact event. Chronostratigraphic, lithostratigraphic and biostratigraphic framework is from Liu (2007). Absolute dates are from Wartho et al. (2011) with plotted radiometric data (insert).

The lowermost Mooreville Chalk is gradational with the underlying Eutaw Formation and is generally described as grey to green-grey, sandy-silty, glauconitic, fossiliferous marl and chalk (Raymond et al., 1988; Mancini and Soen, 1994). The lower Mooreville Chalk is also gradational with the stratigraphically adjacent calcareous, glauconitic, and fossiliferous, fine-grained sand, clay and marl in eastern Alabama. From Liu (2007), the lowermost Mooreville Chalk below the maximum flooding surface was noted to be sandy and gradational, and the transition from calcareous Tombigbee Sand Member to Mooreville Chalk was picked where the calcareous clay-marl content surpassed the sand fraction. However, not all Tombigbee Sand-Mooreville Chalk contacts are judged to be transitional. Aside from sharp, erosive contacts in eastern Mississippi (Mancini and Soen, 1994; Liu, 2007) and in contrast with gradational contacts in Alabama, the closest, undisturbed, and published Mooreville Chalk locality at Catoma Falls overlies sharply the Tombigbee Sand Member, demarcated by a calcareous caprock. Located in northwestern Montgomery County, this locality is located nearly directly down paleodip, approximately 29 km southwest from the center of the Wetumpka impact crater.

Resting atop of a bored, calcite-cemented, echinoid-bearing, and fine-grained sandy hardground contact, the lowermost Mooreville Chalk of Catoma Falls is described by Savrda and King (1993) to be sedimentary package of a calcareous, very fossiliferous, glauconitic sand with an interbedded, sandy chalk. Direct physical evidence of the Wetumpka impact are not currently known at Catoma Falls, but Mooreville Chalk has been a recognized stratigraphic component of the impact beginning with the work of Neathery et al. (1976) where Mooreville Chalk is preserved within topographic lows within the interior of the crater or as graben on the exterior.

However, King and Petruny (2009) suggested that chalk deposits previously attributed to the Mooreville Chalk by Neathery et al. (1976) could be post-impact deposition (i.e., resurge deposits) because of the presence of melted dinoflagellates. Chalk deposits (drilled in well 09-03) located within the interior of the crater were confirmed to be of resurge origin by King et al. (2010), Ormo et al. (2010), and Markin et al. (2011). Furthermore, recent investigation of the isolated chalk outlier to the east of the crater (D. T. King, Jr., personal communication, 2009) is suspected to be of resurge origin; and investigations of mineralogical composition of clays within Elmore county by Clarke (1965) found that this particular chalk outlier contained 15-20 % quartz, 20% kaolinite, 10-15% illite, 20-25% calcite, 1% iron-oxides, and 1-2% heavy minerals. Juxtaposed with basal Tuscaloosa clays in Elmore County with no measureable heavy minerals (Clarke, 1965), and the <1% heavy minerals of Sayers and Uddin (2010) of Tuscaloosa Formation in eastern Alabama, it is clear that this outlier is atypical. Heavy mineral content higher than piedmont-proximal fluvial sediments is unlikely within mid-shelf marls and chinks. Thus, chalk deposits on the exterior could be resurge sediments as well. However, recognition, during this study of rotated, semi-intact blocks of Mooreville Chalk, some coeval Mooreville Chalk was present within the target stratigraphy. Thus, previous assumptions of water depth, coeval deposition, and paleogeographic setting (i.e., King et al., 2006; King et al. 2007) remain valid.

During time of impact, the ancestral eastern Gulf of Mexico was in an active transgressive phase with the main thrust of the transgression centered in the western part of central Alabama and, subsequently, inundating towards the east and northwest (Liu, 2007; Mancini et al., 2008). Evidence from the outcrop belt suggests that, the paleoshoreline transitioned from an east-west trend within the lower Eutaw Formation to a northwest-southeast

trend within the lowermost Mooreville Chalk (King, 1994). However, because the Wetumpka impact occurred within the Mooreville transgressive systems tract and before the maximum flooding surface (e.g., maximum transgression) recognized by Mancini et al. (2008) and Liu (2007), the shoreline was likely in a transitional, general retreating position at time of impact. Moreover, according to Mancini et al. (2008) and Liu (2007), the maximum flooding surface (mfs) of the lower Mooreville Chalk does not coincide with the maximum bathymetric (mfs II) surface of the upper Selma Group identified by Liu (2007). Thus, in concert with observations made Ormö et al. (2010), the depth and distance to shore could be less than previously believed in prior work (i.e., King et al., 2002).

During deposition of the lower Mooreville Chalk, there were two principal siliclastic places of input along the paleoshore line. One was centered near the Alabama-Georgia state line to the east and the other near the northwest corner of Alabama and southern middle Tennessee to the northwest (Mancini et al., 1993). These were roughly coincident, respectively, with where the modern Chattahoochee and Tennessee River valleys intersect the arcuate, Upper Cretaceous outcrop belt. Hypothetically, we can suppose that ancestral equivalents of the Tennessee and rivers existed and these were their entry points into the ancestral Gulf of Mexico. The latter river, the ancestral Chattahoochee River, had some possible depositional influence on the Wetumpka area. Interpreted to be tidally-influenced bay-head delta by Savrda et al. (2003) among many others, the sedimentary reach of the ancestral Chattahoochee River delta extends as far west as Montgomery County within the realm of the Mooreville Chalk-Blufftown Formation (Mancini et al. 1996). Therefore, the Wetumpka area was likely within reach of, at minimum, distal fine-grained prodelta sediments during regressive periods.

Between the principal siliclastic inputs, western to central Alabama were hemi-pelagic bays during deposition of Mooreville Chalk (Mancini et al., 1996; Liu, 2007). Marine depths of the hemi-pelagic shelf at Wetumpka have been previously thought by King et al. (2002) to be between 30 to 100 meters with a hypothetical distance of 40 km to shore. These marine depths are based on paleodepth estimates of Puckett (1991) for marl (35 m) and chalk (65-100 m) inferred from the size of ostracode eyes within marls and chinks of the superjacent Demopolis Chalk. Variance between marl and chalk deposition is thought by Liu (2007) to be a result of Milankovitch-forced climatic cyclicity resulting in marl from increased siliclastic input (regressive?) and chalk from siliclastic starvation (transgressive?). Within the Selma Group, overall biogenic production (i.e., nanoplankton) is thought by Warren and Svarda (1998) and Liu (2007) to be relatively constant.

Although the ancestral Chattahoochee River is likely the principal source for siliclastic sediment within Upper Cretaceous sediments of eastern and central Alabama, other minor rivers and streams likely existed along the paleocoast. Staheli (1976) observed that in a region parallel and proximal to the fall-line stream patterns were dendritic within the piedmont. In particular, river trunks to tributaries were dendritic in pattern and commonly cut across structural trends of the Appalachian Piedmont. However, in the case of the Georgia Piedmont, streams assumed a trellis pattern and were clearly structurally controlled by Appalachian Piedmont structural trends. Staheli (1976) further interpreted that the line between trellis and dendritic pattern represents the maximum extent of the Gulf Coastal plain. The modern dendritic rivers and streams were interpreted by Staheli (1976) to have “etched” into the ancient coastal plain into the underlying piedmont after which the coastal plain sediments eroded to their modern extent, terminating near the fall line. Consequently, similar rivers may have followed southwest-northeast structural

trends of the Appalachian crystalline bedrock (piedmont) north of a narrow post-Tuscaloosa Coastal Plain; however, obviously these rivers had drastically reduced drainage basins probably at the cost of the ancestral Tennessee and Chattahoochee drainage basins as evidenced by the aforementioned, dominant depocenters. Also, this means local fine-grained siliclastic input (i.e., bay muds) was possible and would have been independent of ancestral Chattahoochee sediment.

Finally, the fall line is a prominent physiogeographic feature in the Wetumpka area where stream gradients increase locally and are associated with a monoclinical point of flexure within the Appalachian Piedmont (Staheli, 1976). The fall line has been interpreted to be a contemporaneous physiogeographic feature with the post-Tuscaloosa sediments of the Eutaw Formation based on similarity of ancient stream flow directions to modern ones, mapped along the Tuscaloosa-Eutaw disconformity (Bingham and Frazier, 2004). Although an ancient equivalent of the fall line would likely have some influence on the paleoslope of the sea floor and, in turn, influence impact cratering processes, specific evidence of a contemporaneous fall line at Wetumpka are not currently known. Thus, the possibility for a fall line feature at time of impact remains an open and intriguing question.

In summary, the Wetumpka bolide should have struck shallow seas coeval with deposition of the lower Mooreville Chalk, but before maximum transgression. Utilizing the stratigraphic work of Liu (2007) along with the results and discussion presented within this study, a temporal point of impact is interpreted by this author to occur where the lower Mooreville Chalk and underlying Tombigbee Sand are gradational (e.g., the inner mid-shelf and lower shoreface contact). This is presented in Figure 5 along with a synthesis of other paleogeographic interpretations made by previous authors.

Figure 5. Paleogeographic map of the Wetumpka impact. Paleogeographic reconstruction is based on Mancini and Soens (1994), King (1994), Savrda and Nanson (2003), King et al. (2002), and Liu (2007).

GENERAL METHODOLOGY

The purpose of this study is to examine and build upon the preliminary results and interpretations of King et al. (2010) and Jens Ormö et al. (2010) by detailed drill-core analysis. During the summer of 2009, four wells, including Baillif #1 (well #09-03) and Wadsworth #1 (#09-04), were drilled within the Wetumpka impact crater. These wells were drilled by Boart-Longyear with funding from the NASA grant NNX09AD90G, awarded to David T. King, Jr. and Jens Ormö. Field work of descriptions, logging, core-cleaning, petrography, and initial interpretations were conducted by David T. King, Jr., Jens Ormö, Lucille Petruny, and R. Scott Harris and presented at the Lunar and Planetary Science Conference of 2011 (King et al., 2010; Jens Ormö et al. 2010).

Drill-Core Field Extraction and Processing

Both 09-03 and 09-04 drill-core were extracted with similar methods. Core segments of a maximum five foot (1.52m) length, referred within this volume as “core sections” were cored using water-based, rotary core-drilling. During core-section retrievals or active drilling, some drill-core loss occurred; however, due to the experience of the drillers, loss of drill-core was very low (D. T. King, Jr., personal communications, 2009). Following drill-core extraction, drill-core was washed in the field; thus, most intervals of drill-core did not need further cleaning. Rarely, drilling-mud was injected or compacted on the ends of core sections; however, drilling-mud is easily discerned from original sediment due to high contrast of drilling-mud to original sediments and broken or abraded ends of core sections. All drilling was conducted in English units; thus, preliminary logging was measured in decimal feet.

Well-Site Descriptions and Locations

Drilling of the 09-03 well targeted the “chalk meadow” which was previously proposed by King and Petruny (2009) to possibly be post-impact sediment. For this reason, the well of 09-03 was located at latitude, 32.52595, and longitude, -86.18655 within the “chalk meadow.” A ground-level elevation for the well of 86.3 m was obtained from a 10-m digital elevation model obtained from within ArcGis 9.3.1™ (from http://www.alabamaview.org/10m_DEM.html; accessed on 12 August, 2010; Alabamaview, 2010). This well location is situated within surface exposures of chalky marl; however, surface exposures of the Eutaw Formation are twenty meters to the northwest on the opposing side of a gravel driveway, termed “Baliff’s driveway.” The “Cliffs,” a well-studied and described outcrop of folded-contorted sedimentary megablocks (for example, see Nelson, 2000; King and Ormö, 2007), is located to the north-northwest with a distance of 125 m. Total depth drilled was 296 ft (90.2 m). Well-site geologic map is presented in Figure 6. This map is modified from existing geologic maps of Neathery et al. (1976) and Johnson (2008) based on outcrop descriptions of the “Cliffs” of previously mentioned sources and limited field mapping of marl, Eutaw Formation, and Tuscaloosa Group exposures proximal to the 09-03 well site.

Figure 6. Well-site geologic map for Baillif #1 (09-03). Insert: drilling operations at well-site. Dark green (Kt) is Tuscaloosa Group. Light green (Ke) is Eutaw Formation. Blue is resurge deposits. Map created from limited well-site mapping that was used to modify geologic map of Neathery et al. (1976).

Drilling of the 09-04 core hole targeted the crater floor along the presumed shallow crater edge (personal communication, D. King, 2009); however, the 09-04 well instead penetrated 715 ft (218 m) of predominately sedimentary impactite sands and overturned fold of sedimentary target stratigraphy, interpreted as the overturned flap. The well-site is positioned near the edge of the southeastern crystalline rim/ejecta at latitude, 32.5105, and longitude -86.16145. A ground

level elevation of 85 m is obtained in a similar way as 09-03. Due to limited outcrops and reduced accessibility, no outcrop or field mapping was conducted near 09-04. A well site map (Figure 7) is shown adapted from Johnson (2007).

Figure 7. Well-site geologic map for Wadsworth #1 (09-04). Pre-K is crystalline ejecta and rim. Km? is either Mooreville Chalk or resurge deposition. Modified from Johnson (2007).

Drill-core orientation, preparation, cleaning, and photographic documentation

One of the principal objectives of this study is detailed documentation of drill-core from the 09-03 and 09-04 wells; however, before within some core sections, minor or rare high loss could occur within each section. If no trending or relatable structures, strong textural affinity, similar coloration, or broken, matching-core ends are observed across core section boundaries, the partial core section is positioned in the middle of core section interval as per procedures of Johnson (2007). However, if two core sections share unambiguous similarity versus the other neighboring core section, the partial core section is moved towards the similar core section. Because the core section would then be likely closer to its true position, this is reasoned to provide more accurate core section placement than arbitrary placement in the center.

Following placement of core pieces, drill-core is ideally oriented relative to each other. Typically, drill-core orientation is accomplished in the field by the use of a core orientation tool that grooves the core during drilling (Nelson et al., 1987). However, even under ideal conditions, due to a variety of factors involving the drilling process, orientation error is generally $\pm 11^\circ$ (Nelson et al., 1987), and core sections are sometimes significantly rotated before scribing or grooving (Paulsen, et al., 2002). Therefore, with methodologies discussed by Paulsen et al. (2000 and 2002), drill-core orientation is accomplished by post-drilling, relative re-orientation, correlated with independent structural data. The drill-cores of 09-03 and 09-04 were not oriented in field. However, the non-lithified, generally saturated sediments are poor candidates for conventional orientation techniques such as onsite or tool grooving and scribing. Thus, the 09-03 and 09-04 drill-cores are good candidates for post-drilling core section relative orientation with procedures described below.

Similar to the method of Paulsen et al. (personal communication), drill core pieces were fitted along edges of broken core pieces (Figure 8) relative to an arbitrary starting point. However, unlike Paulsen et al. (2002), orientation was not done with “scribe-lines” (two, differentially colored sets of parallel and straight lines separated by 180° and parallel to the longitudinal axis of the core). The “scribe-line” was avoided because most core pieces were fragile and friable, limiting handling and making scribing long lines difficult and inconsistent. Instead, oriented drill-core pieces were laid on a flat surface and fitted together. Then, a line was drawn across the broken boundaries at the apex of the circular core (see Figure 8). Arbitrary azimuth directions were assigned as follows: down is north, east is right, west is left and, thus, the marked core apex is south; with the exception of X-ray CT Results, notation of dip directions was generally kept to general compass directions (i.e., north, northwest, etc.). Successful orientation was then noted for the core log.

Figure 8. Core fitting and orientation. Top: diagram demonstrating drill-core fitting and orientation. Bottom: demonstration of core-fitting for two small resurge core pieces across fractured ends. Illustration at top is modified from Paulsen et al. (2000).

Successful relative orientation was most successful within the moderately-lithified resurge interval as described in CT methodology. Other unconsolidated to poorly unconsolidated intervals were only oriented if the core pieces were safely capable of handling. Although core pieces within particular core sections were commonly oriented, relative orientation across core section boundaries was commonly problematic. Even if core loss was minimal, unconsolidated core sections commonly had abrasion or disaggregation at the end of

core sections. In these instances, physical fitting was not possible. Although in many instances, probable orientation was still accomplished due to trending oxidation patterns, structural features, and bedding, notated as “probable.” Even with less certain and lengthwise-limited orientation within unconsolidated intervals, orientation was still advantageous for study of deformational features.

Following orientation, drill-core was measured and braced for logging and photographic documentation. Within gaps between core pieces and core box wall, rectangular or cut pieces of closed-cell polystyrene foam were fitted into gaps to brace core pieces from moving. The core boxes are marked at 0.5 ft (15.2 cm) intervals in 09-04 and 0.1 ft (3 cm) intervals in 09-03 directly on top of the box to the right of the core, and depth is written within the interior for each one foot (30.4 cm) increment. However, the resurge interval in 09-03 was measured previously by writing depths directly on the core as part of the work for the abstract by Ormö et al. (2010). Logging and measurements of depth were maintained in English units until data compilation and writing of this volume when English units are converted to scientific units. Demarcation of measurements was based on labeled spacers, field notation of core section bottom depth (i.e., drill run depths). The field depths of core sections are assumed to be correct.

Although drill-core from 09-03 and 09-04 did not generally need further cleaning such as air-compressed abrasive treatment of Johnson (2007), drill-core needed local removal of drilling-mud. With increasing consolidation, drilling-mud was removed correspondingly with brushes, utility knives, and sandpaper. Although spraying water could not be used to elucidate features, the friable nature of most drill-core allowed for the use of brushes to gently reveal internal structures (Figured 9) which then stand out in relief. This additional cleaning helps accentuate structural features.

Figure 9. Example of method of core cleaning method with brushes. From box 19, well 09-03, within an interval personal communication Formation.

Methodology for drill-core photographic documentation is similar to methodology of Johnson (2007) except as follows. The header is reduced to a minimum to increase area photographed thereby increasing resolution for drill-cores. The header includes a scale in cm and 0.1-ft increments, a color strip of yellow, red, and blue to calibrate photographic colors, box, well and depth (Figure 10). A digital, 12 megabyte, Canon Powershot D10 is used for high resolution photographic documentation. Within core boxes as depicted in Figure 10, stratigraphic up is to the left and each subsequent row below the top is increasing in depth. Within documentation and logging, each box is abbreviated “B” and each core row is abbreviated “R” followed by designated numbers, one to five (top to bottom).

Figure 10. Example of photograph-corrected core-box digital photograph with labeled elements.

Because the camera focus was located at the center of the core box, distortion due to “lens bubble” and perspective-derived distortion, loss of focus occurred at the extremities of the core box. “Perspective-derived” distortion is defined a distortion in which view-point appears directly above in center and core ends appear angled towards a “vanishing point.” Core box photographs were corrected for distortions, brightness, and color systematically utilizing the “batch” function for Adobe® Photoshop CS2® as explained by Johnson (2007). Corrections were conducted by the following parameters: filter, lens correction (distort amount = 4, distort coefficient 1:-0.04, distort coefficient: 1.04); brightness (-6%); contrast (+24%); and saturation (+10%). However, following systematic corrections, “perspective-derived” visual distortions still

existed along outer extremities. Also, slight blurring existed at outer edges of photograph. After corrections, for ease of logging, high-resolution digital photographs of core pieces were stitched together into photo composites of 100 ft (30.48 m) in length. However, due to distortions in length, pre-measured ticks were used with Adobe® Photoshop CS2® transform functions to adjust each core piece to the proper length.

Generally, ethical guidelines of Cromeey (2010) are followed for the treatment and presentation of digital imagery. This entails the following summarized, relevant guidelines: (1) correctional processing and image acquisition are identical and adjustments should be simple; (2) image manipulations are conducted across an entire image; (3) cropping is acceptable if it does not exclude contradictory data; (4) internal parts of images should not be altered by cloning or copying; (5) original, unaltered image should be kept; and (6) comparison of digital images should be identically acquired. For some Figures within this text, Adobe® Photoshop CS2® brightness and contrast functions have been used slightly and sparingly in order to accentuate observed features and for the ease of the reader; however, further alterations are < 15% and do not significantly alter the image from the subject's original appearance. Furthermore, due to varying post-drilling saturation of low permeable and high porosity core sections, some core pieces retained water which could make some core pieces relatively darker or lighter.

Drill core description and logging

The 09-03 and 09-04 drill cores were described and logged in nearly identical ways. Due to the shorter length and the importance of the resurge interval, 09-03 was logged at 0.1 ft (3 cm) intervals whereas 09-04 was logged at 0.2 ft (6.1 cm) intervals due to a doubled length. Otherwise, the same characteristics and parameters were recorded for each drill-core with the exception of grain-size which is explained below. For visual estimates of volume (%), visual

estimators of Terry and Chilingar, (1955) are used. Initially, descriptive parameters were recorded on data sheets, and quantitative data were transferred to a Microsoft® Excel® sheet. Additional notes for observations were recorded in notebooks for each core box that build upon or were absent in original field notes. Some selected photographs were taken drill-core features; however, due to the high-resolution core box photographs, features on drill core surfaces did not require further photography in most instances. Internal features did require additional photography.

The following explanations and nomenclature for each parameter for each logged interval are listed below:

- Color: Drill-core was compared to Munsell Color® Rock-color charts (Munsell Color Company, 2009) for standardized names of colors along with appropriate descriptors (i.e., mottled, banded, etc.).
- Grain-size: Using pre-sieved sediment as suggested by Graham (1998), a grain-size comparator was used to visually estimate the most common grain-size according to the Udden-Wentworth scale. For particles larger than boulder-sized (> 4m), descriptive classes of Blair and Macpherson (1999) were used for megaclasts. Grain-sizes were recorded to the nearest 0.5 ϕ (phi) class. For example, medium sand would be recorded as “1.5,” slightly coarse sand would be “1.0” and coarse sand would be “0.5”. Finally, in addition to a visual estimate of common grain-size for 09-04, maximum grain-size (in mm) was recorded because of the presence of conglomerate as suggested by Graham (1998).
- Sorting: Sorting of sediment was estimated from visual estimators (see Figure 5.7, Harwood, 1998) and recorded in a numerical format for well-sorted (0.35),

moderately well-sorted (0.5), moderately-sorted (0.7), poorly-sorted (1.0), very poorly-sorted (2.0) and extremely poorly-sorted (4.0).

- Roundness: A range of common clast roundness was visually estimated and recorded as a numerical value for angular (1), sub-angular (2), sub-round (3), rounded (4), and well-rounded (5).
- Intergranular and fabric: Fabric characteristics, i.e., matrix or grain-supported, were recorded. Character of interstitial material was also recorded. Nomenclature for stratification thicknesses and type follows McKee and Weir (1953) where laminae are <1.0 cm in thickness.
- Inclinations: planar features (i.e., faults, laminae, bedding plane) are measured with a plastic protractor at core surface where viewpoint is parallel to strike.
- Sedimentary Structures: Sedimentary structures are logged with nomenclature from Collinson and Thompson (1989) and with additional visual aids from Ricci (1995).
- Deformational Structures: These structures are recorded with nomenclature for structural discontinuities (i.e. faults, fractures, etc.) from Schultz and Fossen (2008) and for fold and ductile deformation from Twiss and Moores (2007). If sense and amount of offset for faults could be seen, then they are recorded.
- Effervescence: Using at least two HCl drops per 0.5ft (15.2 cm) and 0.4ft (12.2 cm) intervals, respectively for 09-03 and 09-04, the intensity of the reaction is assessed and is assumed to be a rough approximation for relative carbonate content. Each droplet is observed, and using visual estimators of Terry and Chilingar (1953) a percentage is estimated for the density of bubbles at the peak of the acid reaction. This is then classified as follows: marginal, intermittent reaction, 0-2% (bubble

density); very weak, continuous reaction, 2%-5%; weak 5-10%, moderate 10-30%, strong, 30-50%; very strong, 50%-90%, explosive, no visible fluid, fast reaction 90-100%. Each effervescence recording is converted to the number at the high end of the range. Variable reactions are averaged.

- Mineralogy: Grain mineralogy as interpreted from hand lens, occasional smear slide, and optical microscopy. Descriptors of accessory minerals include trace (0-2%), sparse (2-5%), and moderate (5-10%).

In addition to smear slides and hand lens examination, 20 thin-section slides were created (see personal communication able 1). Seven samples were chosen from 09-03 to elucidate resurge matrix, the uppermost chalk of the resurge, structureless sands intercalated in semi-intact Eutaw intervals and the lowermost sand, believed to be the uppermost interval of Tuscaloosa in 09-03. Moving in stratigraphic order from the bottom of 09-04, thirteen samples were selected along approximately 30 ft (9.1 m) or until the first structureless sand is encountered. Oriented samples were cut out in a pie shape and sent to National Petrographic for epoxy impregnation and thin-section production.

Table 1. List of thin-sectioned samples wells marked 09-03 and 09-04 (used in this study).

Thin-section #	Well	Lithology being investigated
03-0.6	09-03	uppermost chalk-resurge
03-57.55	09-03	chalk clast-resurge
03-74.9	09-03	resurge matrix
03-83.5	09-03	resurge matrix
03-87.64	09-03	semi-intact Eutaw sand
03-92.6	09-03	impactite sand
03-207.1	09-03	fluidized impactite sand
03-295.8	09-03	uppermost Tuscaloosa sand
04-339.7	09-04	structureless impactite sand
04-381.6	09-04	structureless impactite sand
04-420.6	09-04	fluidized impactite sand
04-469.6	09-04	Eutaw megaclast
04-481.8	09-04	weakly-laminated impactite sand
04-511.1	09-04	contorted Eutaw personal communication sand
04-577.2	09-04	structureless impactite sand
04-611.3	09-04	structureless impactite sand
04-619.3	09-04	weakly-laminated impactite sand
04-672.9	09-04	contorted Tuscaloosa Sand
04-674.1	09-04	saprolitic, metamorphic clast
04-699.4	09-04	structureless impactite sand

Utilizing 200-350 total point counts per slide was conducted using a 0.2-mm step grid from the each quadrant and the center of the thin section. In addition, shocked minerals and impactite glass were searched for using imagery and descriptions of French (1998) and French and Koeberl (2010). All minerals observed along with general textural features were recorded. Descriptions of thin-section petrography, petrologic terms and scheme of Carrozi (1993). Results of thin-section petrography of drill core 09-04 are presented in the Appendix.

Upon finishing descriptions and notation of drill-core, lithofacies within 09-04 and 09-03 were characterized and logged using LogPlot[®] 3.4. Logged intervals of breccia and megabreccia were also assigned to Tuscaloosa Group, Eutaw Formation, and Mooreville Chalk based on defining characteristics as discussed in Target Stratigraphy. In summary, iron-oxide-stained,

red-orange terrestrial sands and mudstones are assigned to Tuscaloosa. Non-calcareous sands of marine or marginal marine are assigned to the Eutaw Formation. Where primary calcium carbonate (marl) is present and if sands exceed marl, then the unit is assigned to Eutaw Formation (Tombigbee Member). If marl exceeds sand content, then it is assigned to the Mooreville Chalk. Also, bedded or laminated lignite is, based on existing literature, likely diagnostic of Eutaw Formation. Summaries of descriptions and notations of logging are also compiled within the Logplot[®] 3.4 software. Digital logs and photo-composites of 09-03 and 09-04 are attached by CD-ROM.

X-RAY COMPUTED TOMOGRAPHY METHODOLOGY

X-ray computed tomography (CT) is a powerful technique that is relatively new to the geosciences; however, within the past three decades in the fields of petrology, paleontology and 4d experimental studies, X-ray CT have made and are making substantial advances (Carlson et al., 2003; Cnudde et al., 2006). The CT method has a number of crucial advantages. As opposed to classical petrological techniques such as thin-section petrography and polished sections, X-ray CT allows true 3d spatial understanding of a sample in a relatively short period of time with (if properly calibrated and scanned) accurate, quantitative data to accompany excellent, qualitative observations. Moreover, X-ray CT methods are non-destructive and non-invasive which are ideal for valuable, rare specimens of meteorites and fossils such as the resurge interval of the 09-03 drill-core.

In analysis of drill core, X-ray CT is a heavily used and proven technique for drill core applications and study. Flisch and Becker (2003) utilized X-ray CT to identify features, within unconsolidated lake sediment as paleoseismological evidence that traditional X-radiography or purely visual observations would have missed or misinterpreted. Gagnoud et al. (2009) used X-ray CT, in part, to identify and distinguish bioturbated lithofacies from turbidites in their study of

Late-sectioned muds. Furthermore, within the application of drill core analysis, X-ray CT has been used for general sedimentology (Orsi et al., 1994); porosity, permeability, and fluid phase studies within petroleum engineering (Akin and Kovscek, 2003); sedimentological, quantitative studies of mineralogical composition and porosity within sandstones (Long et al., 2009); and comparisons with traditional microscopic techniques and X-ray CT for porosity studies (Van Geet et al., 2003). With an established record of successful results of drill core analysis and for its non-destructive advantage, X-ray CT was the chosen method for study of the fine-grained sediments of the 09-03 resurge interval.

Fundamentals of X-ray CT scanning

Fundamentally, X-ray CT is composed of a source that emits an X-ray fan-shaped beam at a known total energy, a subject of study, and a detector or array of detectors that measure the average energy of the x-ray beam after passing through the subject. Upon passing through the subject of study, a portion of the total energy of the x-ray beam is lost and becomes attenuated. As the X-ray beam sweeps over the subject, measurements derived from attenuation allow average density for a 3d slice of voxels to be calculated by a complex, internal set of algorithms. A subsequent computation allows the 3d voxel slices to be back-projected into a 2-d slice in which each pixel actually represents the average attenuation coefficient (derived from density) of 3d space of voxel (Duliu, 1999). Appropriately, Ketcham and Carlson (2001) analogously compare this to slicing bread in which a series of slices are taken and then can be put together to later recreate a 3-d reconstruction of the subject.

Within X-ray CT, the two basic types of scanners are medical CT and industrial computed tomography. Although medical CT has been utilized for some time within geological studies, medical CT are optimized for living subjects; therefore, medical CT is built to minimize

x-ray exposure to the subject, increased speed, and typically have lower resolution than their industrial counterparts (Duliu, 1999). In contrast to medical CT, which typically has resolution in large fractions of millimeters, industrial CT that includes high resolution, ultra-high resolution, microtomography, and nano-CT typically has scales of observation (field of view) of decimeter, centimeter, millimeter, and sub-millimeter and resolution of 100 micron, 10 micron, 1 micron, and nanometer, respectively (Carlson et al., 2003; Cnudde et al., 2006). Nevertheless, medical CT was utilized in this study because of its accessibility at Auburn University, lower financial cost as compared to industrial CT, and large field of view. Consequently, the entire 28 meters of the resurge interval could be scanned.

Whether the utilized CT machine is industrial or medical, a large variety of configurations exist. However, as discussed by both Duliu (1999) and Ketcham and Carlson (2001) and depicted in Figure 11, all modern X-ray CT machines can be classified according to scan geometries referred to as first through fourth-generation: (I) first-generation is a linear ‘pencil beam’ to detector that translates across the object with subsequent scans at multiple angles; (II) second-generation is similar to first generation but incorporates a fan beam with corresponding arcuate detectors; and (III) third-generation in which the fan beam encompasses the entire object and either the object is rotated or the source and detector are rotated around the object. Referred to in the literature, occasionally, as spiral or helical CT (see description for helical CT in Schreurs et al., 2003; Yazdi and Beaulieu, 2008), Medical CT is considered a fourth-generation technique and consists of a fan beam with a opposite, fixed ring of detectors that revolves around a subject which then translates through the scanning plane. The helical configuration (4th generation) is the configuration utilized in this study.

Figure 11. Schematics for detectors, source and subject utilized within X-ray CT for the geosciences for 1st, 2nd, 3rd, and 4th generation CT scanners. Typically, industrial scanners use 1st, 2nd, and 3rd geometries, and medical (helical) scanners use 4th generation (Ketcham et al., 2001). 4th generation is the configuration utilized in this study. Schematics are from Robb (1982).

Calculating attenuation values in x-ray CT

Because matter, either through specific atomic species or density of a material, attenuates focused X-ray beams, the average density of a particular voxel (the 3d equivalent of a pixel) can be calculated. This attenuation occurs because of three main processes: photoelectric absorption (total absorption of an X-ray photon), Compton scattering (partial absorption of an X-ray photon), and pair production (conversion of an X-ray to a positron-electron pair). Photoelectric absorption, Compton scattering, and pair production are predominant at beam energies of up to 50-100 keV, 5-10 keV, and above 1.02 MeV, respectively. Because photoelectric absorption is more sensitive to the composition of specific atomic species, the best resolution is achieved when lower energies are utilized. However, the use of lower energy beams, as will be discussed later, have consequences for the generation of reconstructed slices (Ketcham, et al. 2001).

Each particular voxel has an intrinsic attenuation coefficient defined by the density of the volume scanned and its constituent atomic species. Fundamentally, calculation of the attenuation coefficient is made possible in a homogeneous material assuming a monochromatic beam by Beer's Law:

$$I = I_0 \exp[-\mu x] \quad (1)$$

where I_0 is the original X-ray intensity in keV, I is the measured x-ray intensity, x is the thickness of the material scanned, and μ is the calculated attenuation coefficient expressed as 1/length. Of course, geological materials are not homogeneous, and thus must be calculated utilizing this equation:

$$I = I_0 \exp[\sum_i (-\mu_i x_i)] \quad (2)$$

where i is an increment of a single material along the linear extent of x_i .

Furthermore, as mentioned, briefly, by Akin and Kovscek (2003) and Van Geet et al. (2003) with more in depth discussion by Ketcham and Carlson (2001), X-ray beams are assumed to be monochromatic from initial calculations (equation 2) to reconstructed 2-d slices by computer algorithms. This assumption allows specific density values to be assigned per pixel and lessens computational complexity but potentially introduces artifacts into the final image (again, see Ketcham and Carlson (2001) on discussion of reconstruction 2-d techniques and problems).

Attenuation of Constituent Minerals

Scanning parameters that could be controlled in this study are the x-ray beam intensity in keV, the amount of current in the x-ray tube in mAmps, field of view, resolution (field of view/amount of pixels) and the scanning time per slice. Within X-ray CT as explained by Duluu (1999) the output parameters are calculated in either CT numbers (industrial scanners) or Hounsfield units (medical scanners). Computed tomography numbers roughly correspond to increasing bulk density in a relative sense (g/cc^2), and Hounsfield units (HU) are scaled so that water and air have a value of 0 and -1000, respectively (for discussion on proper conversion of HU and CT to true density, see Akin and Kovscek, 2003). Finally, pixel resolution is fixed on many medical CT scanners and has limited variability on industrial scanners, but field of view can be controlled (Ketcham and Carlson, 2001). Therefore, true resolution is variable depending on the field of view chosen which can be manually calculated.

In addition, as evident in Beer's law (equation 1 and 2), scanned thickness can be an important parameter in the consequential, measured values of CT and Hounsfield units, degree of noise, and amount of artifacts. However, in this study, in order to change scanned thickness, drill-core would have to be cut to optimal lengths that may have increased resolution and reduced noise but would have compromised one of the main advantages of X-ray CT (non-

destructive analysis). By increasing scan times, noise derived from insufficient beam penetration can be minimized (Duliu, 1999).

In the case of X-ray energy (keV), there will be always some degree of compromise and trial and error to achieve optimal conditions. Prior analysis of attenuation coefficients for anticipated mineral composition allowed correct beam energy to be chosen for an optimal resolution in conjunction with minimized noise of photon starvation. In this study, the targeted x-ray beam energy was ultimately 120 keV. Principal mineralogical constituents were determined from drill-core inspection and reported clay mineralogy from an extra-crater Mooreville Chalk outlier (Clarke, 1965). As demonstrated by Figure 12, the expected, principal mineral phases, quartz, calcite, kaolinite, illite, apatite (OH), and pyrite, show some small separation in their corresponding attenuation coefficients. However, kaolinite and quartz show marginal differences whereas illite has moderately-elevated attenuation values, and calcite, apatite, and pyrite have contrasting values.

Figure 12. Linear Attenuation coefficient (μ) as a function of X-ray beam intensity (keV). The mineral phases shown are expected, principal mineralogical constituents within the scanned interval of core in this study. Obtained from the University of Texas at Austin MuCalcTool at www.ctlab.geo.utexas.edu/software/index.php.

As depicted in Figure 13, attenuation of sample minerals shows that grayscale values of quartz and calcite are similar in appearance within X-ray CT. With a keV setting of 100 keV, calcite, quartz, and kaolin are measured with a mean value of 2390, 1590, and 760 HU, respectively. With a keV setting of 120 keV, calcite, quartz, and kaolin are measured with a mean value of 2060, 1640, and 890 HU, respectively. With a differential of 3.1 x and 2.09 x of calcite and quartz to clay (kaolin) for a keV of 100 and 2.3x and 1.8x differential for a keV of 120, quartz and calcite are far closer in attenuation than to the sample clay. This can be appreciated qualitatively in Figure 13, where clay contrasts with quartz and calcite with darker gray scale values. Thus, based on prior parameters that affect attenuation (mineral phases,

density, and porosity) appreciable dark grayscale values likely indicate qualitatively higher clay content or greater relative porosity.

Figure 13. Attenuation of constituent minerals of the 09-03 resurge interval. This Figure shows 3 samples of the most common mineral constituents of the resurge juxtaposed with the drill-core at two different beam energies (see red arrows). Note similar attenuation values (grayscale values) of quartz and calcite as compared to darker value for kaolinite and greater contrast at lower keV.

The limitations and artifacts in X-ray computed tomography

Furthermore, concentrated glauconite grains impart a generally high attenuation value similar to calcite in appearance. Likewise, pyrites have exceedingly high attenuation values manifest as a near pure white grayscale value. Pyrites are easily differentiated from glauconite and calcite due to starburst artifacts (described below) that involve dark, data-loss shadows and white, false-high attenuation streaks. Starbursts are assumed to be diagnostic for pyritiferous concretions.

For any scientific approach in observation, artifacts are an inescapable reality in both direct and indirect methods. Within X-ray computed tomography, artifacts that emerge in scanned primary cross-sections and 3d, interpolated reconstructions are the main limiting and complicating factor for both quantitative and qualitative objectives. In quantitative and qualitative analysis, proper identification and understanding of artifact generation allow the proper remediation and minimization of artifacts through pre-scanning calibration, proper scanning methodology, and post-computational image remediation. Common artifacts, which are often encountered effects within this study, include the following: (1) beam hardening; (2) partial-volume effects; (3) photon starvation; (4) starbursts; and (5) artifacts due to non-cylindrical cross-section. Ring artifacts are common artifacts with industrial CT scanners and 3rd generation configurations; however, they are not a problem with medical scanners.

Photon Starvation

This artifact manifests in CT images as a mesh of angled streaks (see Figure 14) that degrade the image by increasing the amount of noise. Fundamentally, this artifact arises from an insufficient number of photons due to a lack of penetrating power of the X-ray beam (Yazdi and Beaulieu, 2008). In this study, these artifacts were excluded or minimized by simply increasing

the beam energy (100 keV to 120 keV, 300 mAmp) and increasing exposure time (two seconds per slice), following consultation with the High Resolution X-ray CT Facility at the University of Texas at Austin (M. Colbert, written communication, 2010). However, even with both maximum current (mAmps) and scan-time values, photon starvation artifacts were reduced but not excluded due to the thickness and density of drill cores, particularly within core sections that exceed field of view. Yazdi and Beaulieu (2008) discuss, briefly, an optimal adaptive filtering technique to reduce photon starvation-derived noise; however, the photon starvation technique does not eliminate the artifact and was not utilized in this study.

Beam Hardening

Beam hardening is a ubiquitous artifact in X-ray CT and is particularly troublesome for quantitative analysis. As previously explained by Ketcham and Carlson (2001) and Duluu (1999), X-ray tomography computations are based on the assumption of a monochromatic X-ray beam despite the fact that X-ray sources emit a polychromatic beam. The result is that the scanned study material acts as a filter that removes weaker portions of the beams's X-ray spectrum and raises the average energy of the incident beam (Ketcham and Carlson, 2001; Van Geet et al., 2003). When the effective attenuation coefficients are calculated using Beer's Law, the beam hardening effect manifests in the resulting images as proportionally, higher attenuation values (lighter) near the outside of the object and false, lower attenuation values (darker) in the center of the object as evidenced in Figure 15 (Ketcham and Carlson, 2001; Van Geet et al., 2003). In the case of the longitudinal scans of the drill cores of this study and others, the beam hardening effect manifests as a lightning near the opposing ends of the core in this study or termed "cupping" by Akin and Kovscek (2003) in transverse drill core cross-sections and cylindrical or spherical subjects.

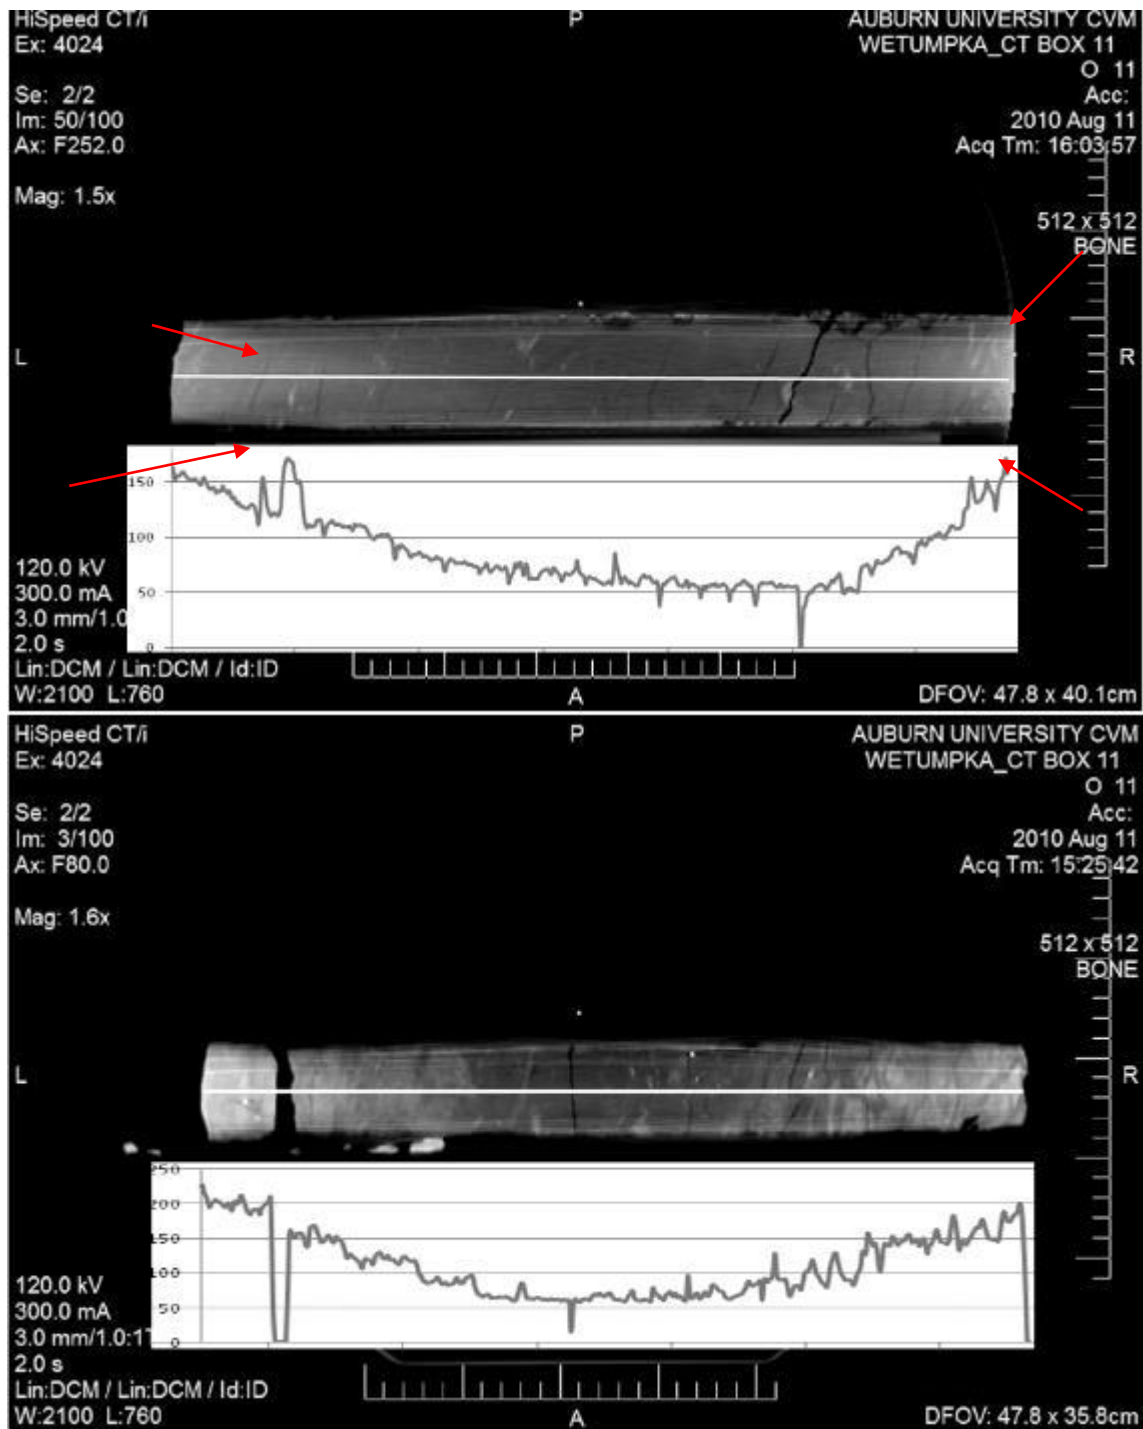

Figure 14. Beam hardening artifacts in X-ray CT. Examples of beam hardening artifacts for 100 keV (top) and 120 keV (bottom). Note the parabolic trend within grayscale analysis for the beam hardening artifact (obtained with National Institute of Health ImageJ 1.44; see Abramoff et al., 2004 for description of ImageJ). Note the typical x-shaped beam hardening pattern within the more homogenous core-section (top, red arrows). For grayscale, black=0; white=250.

Ideally, beam hardening remediation is accomplished during scanning by pre-attenuating the X-ray beam through either a metal foil of aluminum and brass or a wedge of material that surrounds the object with the same attenuation coefficient as the dominant mineral phase of the scanned object (Ketcham and Carlson, 2001; Akin and Kovsky, 2003). However, in the case of medical CT, application of filters in front of the source are not possible as in industrial CT; therefore, in these cases, a carbon fiber or thin (1.0 mm) aluminum core tubing-container is constructed to filter the x-rays (Akin and Kovsky, 2003). Because the pre-filtered X-rays are more attenuated, they have higher average energy. Thus, image definition is reduced as subsequent attenuation is dominated increasingly by Compton scattering resulting in a decrease of noise to signal ratios and less variability of attenuation coefficients. Furthermore, if photon starvation is present in an unfiltered CT scan due to a lack of penetrating power, a CT scan of a filtered object at the same level of energy will only exasperate the photon starvation artifact.

Due to the methodology of this study, beam hardening effects are substantial within CT images. In contrast, to descriptions of “cupping” within previous literature (i.e., Akin and Kovsky, 2003), the cylindrical shape of drill-core impart a general parabolic trend of false low attenuation in the center to normal values at the extremities. Moreover, along the maximum distance of transect, CT images show false low attenuation values from opposing corners. Thus, beam hardening artifacts manifest as a x-shaped artifact anchored at the corners of the drill-core as depicted in Figure 15. Beam hardening is lessened considerably for short core pieces and substantial for core pieces that exceed field of view. Beam hardening are detrimental and prohibitive for quantitative, grayscale analysis (i.e., density) and will likely require complex, computational remediation for grayscale analysis due to variable core length. However, beam-

hardening effects are easy to identify and predictable in position; thus, they are not detrimental for interpretation of qualitative observations.

Partial Volume Effects

As previously mentioned, each pixel of a cross-section is actually an averaged attenuation of a voxel of a real scanned volume. Therefore, a feature of sufficiently contrasting density, atomic species and size that exists beyond the resolution of the scanner can affect the calculated attenuation coefficient (Ketcham and Carlson, 2001). Because geological materials are not truly homogeneous at all scales, CT images always have some degree of blurring that can be attributed to partial volume effects. On the other hand, because features within a scanned volume beyond resolution can affect the final, calculated attenuation value, it is possible to know where those feature exist if they are independently observed by another technique (Ketcham et al. 2001). Other than a slight loss of definition from blurring, partial volume effects are not believed to significantly compromise observations made in this study.

Starbursts

As discussed by Van Geet et al. (2000) and Ketcham and Carlson (2001), if a feature within a scanned volume has high contrast in density to a surrounding matrix, a starburst artifacts forms with dark streaks that do not allow any definition within the emanating shadow (as evident in Figure 15). Typically, these artifacts are created by either sulfides or metal oxides, and the dark streaks are actually secondary radiation emanating from the offending inclusion. If a scanned sample has prolific metal oxides or sulfides (i.e., a pyritiferous mudstone), remediation may include either an aluminum and brass foil filter in front of the detector to screen the secondary radiation, or a drill core can be sheathed in an aluminum-brass foil (Van Geet et al., 2003; Ketcham et al., 2001) for the use of medical computed tomography. However, such filters

can lower beam strength, and if this results in insufficient signal strength, photon starvation, definition-loss can result (Van Geet et al., 2001).

In an attempt to remediate star burst and beam hardening artifacts, an aluminum sheath for the drill-core was fabricated from aluminum containers to approximate an aluminum, core-holder filter of one mm wall thickness (similar to filters described from Akin and Kovscek, 2003). However, following preliminary scans at targeted beam energies (100 and 120 keV; 200 mAmps), photon starvation artifacts were greatly elevated to point where even qualitative observations were not possible. Thus, the constructed filter was abandoned, and following increases in 300 mAmp current and increased scanning time, photon starvation artifacts were reduced to a point where consistent, qualitative observations were possible. Likewise, beam hardening and starbursts appeared less problematic. In fact, starburst artifacts when compared with corresponding areas of the actual drill-core were found to be produced by pyritiferous concretions. Therefore, areas with exceedingly high attenuation values accompanying starburst are assumed to be pyrite concretions.

Ring Artifacts

Ring artifacts are a significant problem within industrial CT scans that use third-generation geometry. When detectors have variable output due to variable external conditions such as temperature or inconsistent performance, an artifact is evident as complete or partial concentric rings centered on the axis of rotation. Remediation of ring artifacts can be removed by software by converting a reconstructed image into polar coordinates and the removal of linear lines. However, there is a possibility that data can be lost if a linear feature is tangential to a circle about the rotational axis (Ketcham, et al. 2001). However, for medical CT, ring artifacts have not been encountered in the scientific literature nor observed by this author for scans of this

study. As medical CT is typically fourth generation configuration, ring artifacts were not a problem for this study.

Artifacts due to non-cylindrical cross-section

The cross-sectional area of CT is circular and internal algorithms assume a roughly circular cross-section; thus, objects that do not have a circular shape and have sharp angular edges produce artifacts in cross-sectional two-dimensional (2d) slices that create a x-shaped artifact that have apparent higher attenuation streaks that connect the longest axes of a 2d shape. Remediation other than alteration of object shape is not known by this author. This is a commonly encountered artifact in the longitudinal scanning of this study (see Figure 14 for example).

Drill-core preparation and X-ray CT scanning procedures

Due to minimal core-loss in the 09-03 drill core, resurge interval, individual core-sections could be carefully re-fitted and therefore oriented relative to each other as per procedures described in drill-core preparation. This orientation was conducted twice to insure no errors in orientation. Within the resurge interval, only at three points were there any uncertainties due to insufficient fitting or changes in drilling methods. Orientations across these points were made possible with trending, inclined-features in either or both visual and X-ray CT observations. Although true (absolute) azimuth orientation of 09-03 drill core is not known, the entire resurge-interval had a relative orientation and individual core sections were rotated clockwise in 90-degree increments when necessary to insure that inclination of features was parallel with CT slices.

For pre-scanning preparation and during scanning, core sections were prepped so that subsequent measurements and observations would be free of unnecessary errors. Because core

sections could, in some instances, exceed the field of view, the volume of space that can be scanned, core sections were centered at the midline of each core box, braced to prevent movement, and depth-measured at the midline for a depth reference point. During scanning, some loss occurred at the ends of a few sections but loss was minimal. Where loss uncommonly occurred, loss was in low single-digit centimeters. This is not believed to have affected observations or interpretations. Finally, each core box, as depicted in Figure 16, was oriented so that the stratigraphic up-direction was always to the right. A thin metal wire was taped across the mid-line to create a depth-reference line for overhead scans and a depth-reference dot for longitudinal scans.

Figure 16. Preparation for X-ray CT. This image shows the orientation and order for longitudinal slices. Entire core boxes were scanned along contiguous slices starting with deepest core row, in this instance B10R5, and systematically progressing towards the most shallow core row (B10R1). Core box is oriented with stratigraphic up to the right (white arrows). Thus, R=Up in longitudinally sliced images. Red arrow shows reference line of core box midline. Blue arrow shows field of view area (DFOV). Green arrow shows pixel resolution. Pink arrow shows beam parameters and scanning time. Yellow arrow shows window (w) and level (l) which control brightness and contrast. In all CT images, tick marks (bottom and left margins) are one cm.

At Auburn University College of Veterinary Medicine, a fourth-generation medical CT scanner was used to take 20 longitudinal (stratigraphic) slices per core section with the following scanning parameters: (1) x-ray beam energy at 100 keV in the upper 3.8 m and 120 keV (kilovolts) below 3.8 m with 300 mA (milliamperes) throughout, (2) scanning time at 2.0 sec per longitudinal slice, and (3) 3-mm section intervals. Also, the field of view was a circular cross-section with a diameter of 47.9 cm for a scanned area of 1800 cm² within a resolution of 512 x 512 pixels. This creates an actual resolution of 0.69 mm per pixel. Because of the methodology utilized in this study, prominent noise and beam hardening artifacts are present; however, the CT images are still far superior to visual observation alone for both qualitative and limited quantitative analysis.

Utilization of X-ray CT data for core logging, observations, and strike and dip data

Following acquisition of X-ray CT data, observations and descriptions were made in tandem with descriptions and observations with the actual drill-core. Due to the fine-grained, low-contrast characteristics of the resurge interval, X-ray CT longitudinal slices provided the bulk of descriptions and observations that allowed deformational and sedimentary structures and delineation of lithofacies. Longitudinal slices are a preferred method to investigate stratigraphic and structural characteristics of drill-core (Ashi, 1997). However, as X-ray CT is an indirect method that only images contrasts of density and mineralogical species, some observations and descriptions could only be accomplished with conventional inspection with hand lens, microscopy, and the “naked eye.” In the event, an observation was made with the “naked eye,” the resulting description, elucidation, or observation is referred to as “visual inspection” or “visually inspected.” Often, it was advantageous to use visual inspection, typically high-resolution photographs, and X-ray CT data simultaneously to investigate the resurge interval.

In a similar fashion as the high-resolution photographs, X-ray CT images extracted with SoundEklon eFilm, a DICOM (Digital Imaging and COmmunications in Medicine) viewer, views were stitched together within Adobe Photoshop CS2 to create a photographic strip log. Within this photographic log, a first track was created with consistent window and level parameters (brightness and contrast controls). In a second track, window and level were adjusted to show structures in the best way. Observations were recorded and sketched for each core section. In addition, movies of contiguous slices of each core box were produced by the Osirix 3.9.4. Osirix 3.9.4 was also used to extract some images. Some Volume Rendering and Multi-planar Reconstruction (MPR) were attempted with Osirix, but, in most instances, noise and artifacts prevented unsatisfactory 3-d reconstructions. Volume rendering creates a volumetric 2-d representation of 3-d data where surfaces defined by attenuation thresholds. MPR is a simpler reconstruction in which the stacking slices are used to reconstruct a volume. Nevertheless, 3-d reconstructions were sometimes good tools to understand spatial relationships of some sedimentological features and structures.

Although noise and artifacts generally prevented quantitative estimates of attenuation and thus density, resolution and definition were sufficient to measure the strike and dip of planar structures and the inclination of linear structures (**sectioned** cylindrical burrows). Measurements of strike and dip data were accomplished by first establishing an arbitrary north from which an azimuth would be measured. Looking directly into the core box oriented stratigraphically became “north or 000 bearing.” Thus, for purposes of X-ray CT images, east (090°) was defined as right or “foot” for CT; south (180°) was defined as looking out of the core box or posterior for CT, and west (270°) was defined as left or “head” for CT. Utilizing Osirix and its 2-d MPR function, quantitative measure of strikes and dips were obtained (Figure 17). The 2-d MPR

Figure 17. Acquisition of strike and dip utilizing Osirix and X-ray CT data. Top screen capture shows strike measurement. Bottom screen capture shows dip angle and direction measure. Top left panel shows strike direction. Bottom left panel shows dip angle. Right panel shows overhead view and helps determine dip direction. In this example, A = north; S = east; I = west; P = south; and R = up.

09-03 DRILL-CORE RESULTS

The 09-03 drill-core is comprised of three basic genetic facies. From the top to bottom, they are: (1) resurge-deposited calcareous, glauconitic, sandy mudstone (marl) with sedimentary structures of both gravity and aqueous flow; (2) a semi-intact, rotated and folded Eutaw-Tuscaloosa mega-block formed by mega-slumping/avalanche deposition; and (3) impactite sand injection and in-situ disaggregation situated within the Eutaw-Tuscaloosa megablock. The latter two genetic facies comprise what is called herein the ‘megablock and impactite sand complex.’ The three fundamental genetic facies of the 09-03 and their constituent lithofacies are reported below in stratigraphic order (i.e., oldest first) along with relevant observations of structural, sedimentological, and stratigraphic characteristics.

Megablock and Impactite Sand Complex: General Stratigraphic and Sedimentological Characteristics

The interval of interbedded semi-intact Eutaw-Tuscaloosa and impactite sands begins at 90.2 meters (at the end of the hole) and is continuous to a depth of 25 meters; however, based on criteria presented elsewhere, only the lowermost 0.5 meter can be attributed specifically to the Tuscaloosa Group. As shown in Figures 17a and 17b, the Eutaw mega-block is punctuated by three significant zones of disturbance: (1) disrupted zone 3 (*dz3*) of interpreted disaggregation and brecciation underlying the resurge interval, delineated from 25 m to 34.5 m depth; (2) disrupted zone 2 (*dz2*) of injected impactite sands, fluidization, and brittle-deformation, delineated from 56 m to 66 m depth; and (3) disrupted zone 1 (*dz1*) of possibly both injected impactite sands and brecciation of indeterminate length at the base of drilled interval, delineated from 84 m to 90.2 m depth.

Again, as depicted within Figure 18, general sedimentological and stratigraphic trends include a general fining-upward from gravelly, coarse sands at base to fine to very-fine-grained sands near the top of the whole of the megablock-impactite interval along with a less well-defined increasing of sorting upwards. Further, with increasing depth, the Eutaw-part of the mega-block is increasingly more indurated owing to iron-oxide cementation and sparse-interstitial, authigenic silica cementation. With increasing depth, decreasing levels of bioturbation were observed along with marginally-greater feldspar content and increasing heavy mineral content (iron-oxide grains) and general increasing of grain angularity. Furthermore, the general fining-upward interval is comprised by sub-intervals of fining-upward sequences of approximately 1-6 meters in thickness (as depicted in Figure 18). Figure 19 shows the stratigraphic column of the 09-03 megablock-impactite sand complex.

Dark green = Tuscaloosa megablock (near base of column at 90 meters). Orange = impactite sands. Orange-red = clastic dikes. For lithofacies descriptions, see text. Depth is in meters.

Lithofacies Characterization

Within the drill-core interval, the Eutaw-Tuscaloosa megablock comprises nine descriptive lithofacies: *micaceous, massive Tuscaloosa sand (T1)*; *trough cross-bedded sand (E6)*; *bioturbated, cross-laminated sand (E7)*; *bioturbated, massive sand (E1)*; *bioturbated, interbedded sand and mud (E2)*; *sheared, bioturbated sand (E8)*; and *sheared, cross-laminated sands; fluidized sand*. The impactite sands comprises 3 fundamental lithofacies: *structureless, impactite sands (D1)*; *fluidized impactite sands (D3)* and *clastic dikes (D2)*. These lithofacies are presented below in stratigraphic order of appearance (see Figure 19).

Micaceous, Massive Tuscaloosa Sand (T1)

This lithofacies is only present at the base of the drilled interval and is 0.5 meters thick, but the contact with the overlying lithofacies is indistinct and gradational, mixing with the overlying brecciated, poorly-consolidated, Eutaw-derived sandstone. Sedimentologically, this interval is a white-pink, poorly-sorted, very micaceous, subfeldspathic arenite. This lithofacies is poorly consolidated owing to sparse silica-cementation in which interstitial interpreted-impact-derived glasses have partially or wholly devitrified into secondary chalcedony, chert, microcrystalline quartz, and fibrous chlorite (Figure 20). Moreover, layered muscovite grains show anomalous alteration with frayed, splayed edges decorated with either chalcedony or low-birefringence chlorite (Figure 20).

Although this lithofacies possesses similar textural characteristics for Tuscaloosa Group, it could be Tuscaloosa-derived, disaggregated, impactite sand because no sedimentary structures (e.g., cross-stratification) are observed.

Figure 20. Thin-section petrography of *T1 lithofacies*. a,b. Plane-light (ppl) and Crossed-polars (xpl), respectively, of devitrified glass. Note floating contacts of framework grains. c. Close-up of altered muscovite books and interstitial chalcedony. Note 'splayed' ends of altered muscovite. d, e. Xpl and ppl, respectively, of glass? devitrified to chlorite. Chl=Chlorite, Chy=Chalcedony, Cht=Chert, and m=muscovite.

Structureless, Impactite Sands (DI)

All intervals of this lithofacies are structureless sands without any evidence for primary sedimentary structures or bioturbation, specifically intact burrows. Moreover, all intervals of structureless impactite sands are constrained within the zones of disruption. Thin sections from 28.2 and 63.1 m were examined for petrography of this lithofacies. Framework grains are moderately fractured and contain significant heavy minerals not observed within semi-intact intervals of the Eutaw-Tuscaloosa mega-block. The *DI* lithofacies are texturally-diverse dependent upon which zone of disruption they are found, as discussed below.

The *DI* lithofacies for the disrupted zone 1 are enigmatic as compared to other parts of this core. This lithofacies is a greenish-gray-brown, very homogeneous, moderately-sorted, sub-angular to sub-round, medium-grained sand intercalated with a yellow-tan bioturbated, Eutaw-derived sand breccia (Figure 21). The breccia clasts of Eutaw sand are sparse, widely dispersed. In one place, a large, 2.7 m boulder of fluidized and overturned basal Eutaw-derived sediment occurs in this lithofacies Eutaw-derived sands are gradational and mixed with the *DI* sediment of the *dz1* near the base. The matrix sands of *dz1* do not have any sedimentological equivalents. Eutaw sands with the aforementioned characteristics have not been observed in either drill-cores of this study or existing literature.

The *DI* lithofacies is mainly confined to the lowermost disturbed zone, *dz1*; however, a short, isolated, and texturally identical interval is located at 66.14 to 66.39 meters occurring as injected impactite sand within a network of sub-horizontal, dilational dikelets. These impactite sands are distinct from surrounding impactite sands due to their good sorting and/or marginal effervescence in HCl. Also, a gray, metamorphic rock fragment (<1cm) of indeterminate specific lithology was found within this injected impactite sand.

= 0.1' (3

Figure 21. Selected core intervals and thin-section petrography of *D1* lithofacies. a. *dz3* example of *D1* lithofacies. b. *dz2* example of *D1* lithofacies with fluidized eutaw sands at top. c. *dz1* example of *D1* lithofacies. Note *E1* breccia (white-dotted line). d,e. Thin-section (92.6' depth) showing subhedral garnet (right, high relief) and biotite (left, olive green). f, g. Thin-section (207.1' depth) showing interstitial devitrified glass within *D1/D2* lithofacies. Note entrained quartz and glauconite (round, green) grains located within the devitrified glass. Also, note fractures and injection of matrix/devitrified glass (top).

In contrast to other intervals of 09-03 where interstitial finer-grained sediment is common, interstitial volume of the *DI* sands is exceptionally clean (lacks matrix) in the *dz1*. On the other hand, the *DI* of the disrupted zone 1 exhibits very low permeability and marginal acid effervescence as determined from HCl drop tests. Thus, this impactite sand is weakly cemented by calcium carbonate and, possibly, silica cement; however, these impactite sands remain slightly friable.

The *DI* intervals within disrupted zone 2 are tan poorly-sorted, sub-angular to sub-rounded, bimodal to polymodal, massive subfeldspathic to quartzose, medium-grained to gravelly coarse sands with sparse pebble-sized clay rip-ups to cobble-sized fine-grained bioturbated eutaw breccia. The *DI* intervals of *DZ2* are interbedded and gradational with fluidized sands in which boundaries are mostly indistinct. The coarse-grained sediment and mottled, iron-oxide staining and cementation make this lithofacies difficult to distinguish from the fluidized sand lithofacies. Furthermore, thin-section petrography reveals similar sparse silica-cementation as the *T1* interval with a greater amount of grain fracturing. Also, the impactite sands of the *DZ2* interval appear to be coarser than both overlying and underlying Eutaw mega-block intervals; therefore, it is likely that this interval is sourced from below where coarse-grained sediment is common.

The *DI* intervals within disrupted zone 2 are light tan-gray, friable, bimodal, micaceous, moderately-sorted, homogeneous, quartzose sands with sparse feldspar content and rare, weathered biotite. Sparse, barely recognizable, fragmentary clay-lined burrows are observed, which contrast to the typical well-preserved ichnofossils of the Eutaw sands. Although structureless, the *DI* intervals of the *DZ3* are texturally and mineralogically similar in appearance to semi-intact underlying

bioturbated Eutaw sands and appear to form a matrix in between heavily folded breccia and mega-breccia near the top of the Eutaw-Tuscaloosa megablock.

Bioturbated, Massive Sand (E1); Bioturbated, Interbedded Sands and Muds (E2); Bioturbated Muddy Sands (E3)

Bioturbated, massive sand is the predominant lithofacies of the cored interval of 09-03.

Texturally, the *E1* lithofacies is diverse, but all intervals of *E1* contain intact, well-preserved cylindrical, sub-vertical burrows (original orientation) composed of nodose clay-peloids, which were indentified as Callianassid burrows of *Ophiomorpha nodosa* (cf. Pollard, 1993 and Figure. 22).

Other simple clay-lined burrows that do not appear to be composed of nodose clay pellets are likely to be *Ophiomorpha* sp. as well. *Ophiomorpha* can range from 1 to 3 cm in diameter, are commonly oblique to the vertical axis of the drill-core, may be mantled by heavy minerals (iron-oxide grains), and occasionally diverge into multiple bulbs or shafts. Furthermore, *Macaronichnus* are considerably subordinate in number to *Ophiomorpha* and are concentrated directly above *dz1* within cross-stratified lithofacies and associated *E1* facies.

Texturally, all intervals of *E1* are massive, and occasionally contain bi-modal grain-size. All intervals have sparse relict primary sedimentary structures (i.e., fragmentary mud-drapes, clay laminae, and cross-stratification) and a dominant yellow-tan staining along with common purple-pink color mottling (may be from manganese-oxides). Grain-size, grain-shape, and consolidation appear to generally follow previously reported trends. Above *dz2*, *E1* is generally a medium to very fine-grained, sub-rounded to rounded, moderately well-sorted to well-sorted sand with disseminated grains of lignite and iron-oxides in association with similarly comprised lamination in stratigraphically-adjacent intervals (Figure 22). Below *dz2*, *E1* is generally a variably tan to

Figure 22. *Bioturbated, Massive Sand (E1), Bioturbated, Interbedded Sands and Muds (E2), and Bioturbated Muddy Sands (E3) selected core intervals. a. E1 lithofacies (upper Eutaw). Note typical longitudinal cross-sectioned *Ophiomorpha nodosa* (Op), “coffee ground” texture of disseminated iron-oxide grains, and isolated limonite nodule. b. E3 lithofacies (upper Eutaw). Note purplish-pink mottling typical of upper Eutaw sands and muds. c. E2 lithofacies (upper Eutaw). This is a typical example of bioturbated relict lamination and heavily-burrowed, light gray clay bed. Note that there is some pink-purple mottling near top. d. E2(top)/E1(bottom) lithofacies (lower Eutaw-Tuscaloosa megablock).*

orange-brown to reddish-brown, medium to coarse-grained, angular to sub-rounded, moderately to poorly-sorted sands and is generally less common in the lower interval of 09-03 below *dz2*.

Bioturbated, Interbedded Sands and Muds (E2) are gradational with *E1* and are distinguished from *E1* by semi-intact, burrowed, intercalated clay-laminae and beds as shown in Figure 22. From just above *dz1* upward to a depth of 35 m (upper part of megablock), clay laminae, bedding, and *Ophiomorpha* pellets are a very light gray to nearly white, that are non-expansive when wet; thusly, clay is likely mostly kaolinite in composition. Moreover, similarly to *E1*, sands are stained a yellow-tan and are occasionally stained a mottled, purplish-pink. Whereas upper *E2* intervals have light gray to white clay content and occasional purple-pinkish mottles, the *E2* intervals from *dz2* downward toward the base of the Eutaw interval appear to be more variable in shade of gray, locally expansive, commonly have a fringing, red iron-oxide stain, and are devoid of purple-pink mottles. Therefore, clay color along with iron-oxide staining may be an approximate guide for position within the Eutaw Formation at Wetumpka.

Bioturbated, Muddy Sands (*E3*) are texturally identical to *E2* along with *E2* trends except greater clay-content overall and mixing due to bioturbation. Original primary structures are nearly destroyed or unrecognizable.

Fluidized Sands (E4) and Fluidized Impactite Sands (D2)

Fluidized sediments are found within *dz1* and *dz2*. Within these disrupted zones, intervals abutted with *D1* show highly ductile deformation in which sediments have been deformed into subtle, tight, disharmonic, polyclinal, and recumbent folds (Figure 23). Where primary sedimentary structures and burrows can be resolved (i.e., cross-lamination), the intervals are delineated as *E4*; however, if no primary structures can be resolved but folding can still be resolved, the intervals are assigned *D2*. *E4* and *D2* are gradational with each other and thus

Figure 23. Brittle-Ductile-Fluidized Transition of 09-03 *dz2* interval. This Figure illustrates the gradual transition with increasing depth from a. brittle deformation (conjugate micro-faulting) of *E7*, b. ductile deformation (convolute lamination, black arrow) of *E8*, c. fluidization of semi-intact cross-lamination (black arrow), and d. subtle fluidization (black arrows) of impactite sands of *D2/D1*. Within b, thin dilatational fractures can be seen cutting across deformed fabric of *E7* and a broken sectioned pink feldspar crystal occurs in this interval (white arrow).

distinguishing between these lithofacies is problematic. Observations of these lithofacies do not reveal conclusively whether *D1* precede *D2* or *D1* is derived from fully-churned *E4* and *D2*; however, within one transitional interval of *D2*, thin-section petrography reveal possible interstitial glasses (Figure 21 f. and g.), greater feldspathic content in sand and pebbles, and greater heavy-mineral content. This suggests that some impactite sands, which may have been injected, must have formed prior to this deformation.

Bioturbated, Cross-laminated Sands (E5)

E5 intervals appear to be transitional between *E1* and *E6* (trough cross-bedding, *E6*, described below). Within *E5* intervals, cross-lamination is usually subtly expressed, a result of incomplete bioturbation or non-contrasting laminae. Cross-lamination are commonly comprised of limonitic, lignitic, and clay-pelloidal laminae. In the case of heavy mineral laminae (iron-oxides), laminae are either low-angle, cross-bedded, current-rippled, laminated by discrete heavy mineral laminae, or slightly diffuse and convoluted laminae of heavy minerals. Moreover, observations with hand lens show bimodal, alternating grain-size within sedimentary fabric, possible reactivation surfaces, sparse mud-drapes, and concave cross-bed set boundaries; possibly, this suggests that this facies is originally tidally-influenced, trough cross-bedded.

Textural character of this facies follows previously mentioned trends and is gradational with neighboring *E1* intervals.

Trough Cross-bedding (E6)

Due to pervasive bioturbation and low-contrast lamination, this lithofacies is relatively uncommon and is gradational with *E5*. The *E6* lithofacies is texturally different depending upon stratigraphic position: above *dz2* (upper part of megablock), this lithofacies is yellow-tan to white, alternating well-sorted to moderately-sorted, medium to very fine-grained, herring-bone,

trough cross-stratified sand; below *dz2* (lower part of megablock, this lithofacies is a variably red-brown to yellow-tan to tan and brown, poorly-consolidated (iron-oxide cemented), moderately to poorly sorted, medium to coarse-grained, herring-boned, trough cross-bedded gravelly sand. *E6* intervals are interpreted to trough cross-bedding for similar reasons as *E5*.

Within the upper intervals of *E6*, well-sorted, laminated and thin foresets exhibit a false greenish-brownish coloration and very-weak acid effervescence (Figure 24a), which is interpreted to be drilling-mud infiltration sourced from overlying resurge marl. Mud-infiltration occurs only in alternating thin foresets of very-well sorted sands where as white, non-infiltrated thin foresets are observed to show more moderate sorting and greater interstitial mud content. These well-sorted to moderately-sorted couplets along with evidence for some current reversals (herring-bone cross-stratification) are interpreted to indicate tidal-channel or tidal-delta deposition.

Figure 24. Selected examples of *E5* and *E6* lithofacies. a. Herring-bone cross-bedding of upper Eutaw interval of megablock. b. Bioturbated, cross-laminated interval of upper Eutaw interval of megablock. c. Bioturbated, medium to coarse-grained interval of lower Eutaw interval of megablock. d. Rotated, herring-bone *E6* breccia clast., which is located within *dz1*. Black arrow is transected *Ophiomorpha* burrow. This mega-clast is delineated in Figure 19.

Within the lower intervals of *E6*, trough cross-bedding texturally contrast considerably with upper part of megablock intervals. The lower *E6* intervals appear to be a basal unit which fine-upward conspicuously, but due to the mottled iron-oxide staining and cementation and poor-sorting, individual foresets are more difficult to distinguish within drill-core. This lower expression of *E6* lithofacies is gradational with *E1* in bioturbated, coarser intervals and gradational with *E5* in finer, upward sub-intervals of the overarching fining-upward sequences.

At the top of the *E6* interval, a rippled top is identified at 37.8- m depth with only 6 cm thickness. This unit consists of cross-hummocky, well-sorted, fine-grained lamination overlain with a rippled top and a 1 cm clay flaser thin bed. Thus, this thin bed is interpreted by this author to be a thin tempestite. This unit caps a sequence of *E5* and *E6* lithofacies. However, this unit provides an important, unambiguous bedding orientation and up/down indicator, which reveals at 37.8 m depth, an upright orientation and rotation of 22 degrees.

Clastic Dike (D3)

Clastic Dikes (*D3*) are most common within *dz2*; outside of the *dz2*, clastic dikes only exist as thin <1cm along planar, tabular features which could be interpreted alternatively as compaction bands. Following examination of injected sands, the following interpretations (cf. Figure 25) were made about these clastic dikes: (1) dilation of pre-existing strata in which textural aspects, coloration, and structural features can be traced vertically across the clastic dike, (2) within the dike, there is a subtle fining and better sorting towards dike walls, (3) an occasional mud or sand laminae 'liner' lies along one or both dike walls, and (4) there is an absence of primary sedimentary or deformational structures. Furthermore, *D3* lithofacies contrast texturally with and are typically finer-grained and better-sorted than host sediments (Figure 25). Rarely, clastic dikes are massive versions of host sediments (Figure 25d.);

Figure 25. Selected Intervals of *D3* lithofacies. a. Typical example of thin fine-grained *D3*. Dashed lines show points of separation and dilation. Black arrow points out a cross-cut ductile deformational fabric (convoluted lamination) by clastic dike. Dashed arrow marks an interpreted flow b, c. Typical thick *D3*. Dashed lines delineate fine-grained liner, sub-horizontal to dike walls (see also d.). White dashed arrow marks an interpreted turbulent flow. Black dashed arrow marks an interpreted main flow. d. Interpreted clastic dike resulting from local, strong folding suggested by curvature of lamination (black arrows).

in these cases, neighboring structural trends indicate substantive, local folding. Therefore, these are interpreted to be local dikes derived from folding and consequential over-pressuring and liquefaction of sediments within the relatively tight fold increased, relative grain-size (coarse or very coarse grain-size) and moderately to poorly sorting. The thin clastic dikes (<5 cm) are fine to very-fined grained sand and are well to well sorted. Secondly, most *D3* are <30 degrees to the horizontal plane and sub-tabular in shape. Fine, thin clastic dikes are more irregular in their shape and can, in some instances, appear to be branching. Thirdly, in one large *D3* interval (60.1-60.26 m), evidence of turbulence can be discerned. Namely, a fine-grained, dark-brown ‘eddy-like feature’ is apparent as a shadow behind the slightly-rotated, upper wall of this clastic dike (Figure 25). Using these subtle, turbulently formed features a stratigraphically upward direction of injection can be interpreted. Finally, all clastic dikes cross-cut pre-existing deformational fabrics, with the exception of rare irregular dikes which may be merely a case of preferential rupturing along pre-existing micro-fault sets. This strongly suggests that *D3* lithofacies are derived from a secondary deformation/disruptional event, separated from the primary deformation/disruption event by an unknown interval of time.

Sheared, Bioturbated sands (E7); Sheared, Cross-laminated Sands (E8)

Although local ductile deformation (convolute lamination) and brittle deformation (micro-faulting and fracturing) occur throughout the 09-03 core, these facies are delineated based on the presence of systematic and pervasive structural deformation. Both *E7* and *E8* are superimposed upon previously-described lithofacies of the Eutaw megablock and are constrained to *dz1* and *dz2*. Where cross-stratification can be observed, the appropriate interval is delineated as *E8*. Conversely, if relict lamination and burrows are observed to be structurally deformed, the appropriate intervals are delineated as *D4*.

Brittle deformation demonstrated by interval 56.6 to 58 meters is characterized by conjugate, micro-fault sets of both reverse thrust and normal faulting (Figure 23a). Brittle deformation gradually transitions into increasingly ductile deformation (versus brittle deformation) until deformation is wholly characterized by the disharmonic, tight, recumbent folding of lithofacies of *D2* (Figure 23). These aforementioned brittle to ductile transitions overlie *D1* intervals in *dz1* and *dz2*, occupying the upper portion of disrupted zones.

Unrelated to structural deformation, the aforementioned faulted-interval from 56.6 to 58 meters is mineralogically distinct from other cross-lamination intervals. Along with red, well-sorted, fine-grained cross-laminated sand, both clay laminae and thick laminae of inter-mixed glauconite, green mica, and heavy minerals exist interlaminated with quartzose sands (Figure 23a).

A thin interval that provides an up-down indicator is identified only at 37.8 m depth with only 6 cm thickness. This unit consists of cross-hummocky, well-sorted, fine-grained lamination overlain with a rippled top and a 1 cm clay flaser thin bed. Thus, this unit is interpreted to be a thin tempestite. This unit caps a sequence of *E5* and *E6* lithofacies. However, this unit provides an important, unambiguous bedding orientation and up/down indicator. This unit reveals at 37.8 depth an upright orientation and rotation of 22 degrees.

Deformational and Structural Observations of the Megablock-Impactite Sand Complex

Precise orientation of the whole drill-core was generally not possible because the drilling method did not allow it. Typically, drill-core segments lying in the core boxes could be oriented relative to one another by looking at the breaks between ends of core pieces. By rotating the core to conform to as many consistent end-breaks as possible, localized folds could be discerned if lamination and bedding are present in the clastic intervals. However, direction of dip within

the sub-resurge sediments cannot be utilized consistently to discern structural geometry at intervals greater than 3 meters. An exception occurs across the span from box 21 to 22 (55.5 to 59.7 m depth and Figure 23a) where drill core was oriented across core section boundaries within a high density, conjugate set of faults. After orientation of drill core, measurements of these micro-faults reveal systematic, sub-parallel dipping-direction of conjugate, systematic faults with apparent normal and reverse offsets.

Across the entire megablock-impactite sand interval, measurements of inclinations reveal some general trends, depicted in Figure 26. The following observations are made from density of features, curve-fitting with a sixth order polynomial trend, and linear trends, and juxtaposition with disrupted zones (for discussion on curvilinear regression see Davis, 2002). The exceptional high order polynomial was used because it provided the best least-squared mean (R^2 value). The following observations were made regarding inclinations:

- (1) a general sinusoidal trend within inclination of all lamination and bedding planes and are moderately constrained between 10 and 50 degrees,
- (2) two clusters of shallowing faults and fractures directly above $dz1$ and $dz2$,
- (3) a general shallowing of clastic dike inclination with increasing depth,
- (4) a peak to inflection point relationship of the fracture-fault polynomial trend with the bedding-lamination polynomial trend.

Figure 26. Inclination trends of the Tuscaloosa-Eutaw megablock-impactite sand complex. Red circle marks are rotated subhorizontal features. Sinusoidal lines are sixth order polynomial trends. Purple arrows show two shallowing-downward trends with increasing depth of brittle deformation (near or within top of *dz1* and *dz2*). Black arrow shows shallowing trend with increasing depth for dilatational deformation (clastic dikes). Dashed purple lines show relationship of bedding and lamination inclinations with fracture and fault inclinations. Depths (left margin) are in meters.

Furthermore, observations within the core reveal a general, intercalated transition from brittle-dominated deformation to ductile-dominated deformation and, finally, fluidization and brecciation (Figure 23). This transition is most evident above *dz2*; however a similar transition can be discerned above *dz1*. The brittle-ductile transition above *dz1* is more difficult to observe due to iron-oxide cementation and staining and brecciation of the ductile to fluidization interval (Figure 23). Internally, breccia and mega-breccia within *D1* and *D2* show considerable rotation as evidenced by upside-down *Ophiomorpha nodosa* (overturned basal bulb) and rotated cross-bedding and a near vertical cross-bed set boundary (Figure 24).

Apparent Eutaw Megablock Thickness

The total thickness of the Eutaw-Tuscaloosa megablock–impactite complex is 64.9 m. This total thickness is thicker than the general reported thickness of Eutaw Formation by more than a factor of 2. Within disrupted zones, brecciation, severe folding and fluidization, and injected impactite sands and clastic dikes have likely substantially increased the apparent thickness. Therefore, removal of the disrupted zones (25.5 m) shows an apparent thickness of 39.4 m for the Eutaw megablock. Utilizing the mean inclination of rotated sub-horizontal bedding (30.3°), the following simple trigonometric function was used to estimate true thickness:

$$t_a \cos \beta = t_t \quad (3)$$

where t_a =apparent thickness from core, β =angle of bedding inclination, and t_t = to true thickness. The minimum estimated thickness of the rotated Eutaw thickness of the mega-block becomes 34 meters.

Thickening or thinning of apparent thickness is an indicator of faulting. Reverse and thrust faulting that intersect the cored interval would thicken the apparent thickness of the megablock due to the repetition of strata. However, unambiguous repetition of lithofacies is not

apparent, and lower lithofacies are mostly distinctive from upper megablock sands by grain-size and greater preservation of primary sedimentary structures. On the other hand, grain-size coarsens briefly within heavily deformed intervals of the *dz2* and then fines again below. Therefore, a limited repetition is possible, but the Eutaw Formation is highly heterolithic and therefore, this is not strong evidence for repetition. This is especially true considering that the distinctive cross-laminated, glauconitic lithofacies of *E8* (sectioned 56 m to 58 m) is not repeated below *dz2*.

Conversely, normal faulting that intersects the cored interval would result in reduced thickness of the megablock. However, distinctive bedding or sequences of bedding do not reveal an unambiguous omission from the cored interval. This is not evidence against normal faulting because of the somewhat incomplete nature of the cored interval and the heterolithic nature of the Eutaw Formation.

Resurge General Visual Observations

Qualitative observations of visual estimates of grain-size reveal a general fining-upward along with local fining and coarsening upward subsets (Figure 18). Sorting trends show a slight decreasing upward overall, but upward parts of the resurge interval show an apparent more well-sorted calcareous silt and clay. The general observations of grain-size are believed to be reasonably accurate as compared to thin-section petrography. Locally, the sand fraction shows moderate grading.

Upon visual inspection and thin-section petrography, the principal mineralogy includes biogenic and recrystallized calcite, detrital quartz, clay, detrital glauconite, and framboidal pyrite. Detrital feldspar of both plagioclase and potassium feldspar are subordinate (<10%) in proportion, and heavy minerals appear to be elevated in thin section petrography as compared to

in-place Mooreville Chalk and Eutaw Formation. Glauconite is disseminated throughout the resurge interval; however, detrital, resurge-matrix glauconite is concentrated only in the basal lithofacies. Otherwise, within the drill-core, glauconite appears to be concentrated (>20%) only within transported clasts of calcite-cemented, Mooreville Chalk-Eutaw Formation contact (i.e., at the top of the Tombigbee Sand Member of the Eutaw) and Mooreville Chalk, or uncommonly as detrital glauconite within cross-stratification.

Consequently, due to the mineralogy of the resurge interval, the marly interval is predominately and in places bluish, green-gray color. Where chalky blocks and clasts are encountered, coloration can be a light gray or near white. Above approximately 6.1 m depth, the resurge interval is increasingly oxidized with red-orange staining presumably from the oxidation of pyrites. Also, resurge-matrix transitions into a light tan-gray color within the oxidized zone with prevalent white caliche nodules within the uppermost 2 meters.

Aside from grain-size, mineralogy, and coloration, sedimentary structures and fabrics are the most distinctive features within the resurge interval. Principally with sedimentary structures and fabrics, stratigraphic units can be delineated. With visual inspection alone, sedimentary structures and fabrics are enigmatic and anomalous within the fine-grained sediment that characterizes the resurge interval. In conjunction with X-ray CT, however, clear, unambiguous structures are observed that enable stratigraphic patterns and mode of deposition to be interpreted. Sedimentary structures and fabrics, stratigraphic patterns, and owing stratigraphic units are reported below.

Lithofacies Characterization and Stratigraphic Patterns

Utilizing x-ray CT in conjunction with visual inspection of the drill core, Markin et al. (2011) previously reported six lithofacies of the resurge interval. The resurge lithofacies are, in

relative stratigraphic order: *basal shear-mixing zone (R1)*; *matrix-dominated breccias (R2)*; *clast-dominated breccias (R3)*; *transported Mooreville Chalk (R4)*; *poly lithic-laminated matrix (R5)*; and *enigmatic chalk (R6)*. In this study, letter designations in parentheses are used for brevity. In contrast to Markin et al. (2001), *R1* has been renamed herein as the *basal shear-mixing zone* because this is more appropriate.

Differentiation of impact-derived marl-chalk breccia and disaggregated resurge matrix is the main goal of CT studies in this project. As discussed by Markin et al. (2011), utilization of conjugate CT slices (moving between slices), impact-derived mud-chalk breccia can be distinguished from resurge matrix by the following criteria: (1) a general lower attenuation coefficient for impact-derived matrix as compared to intact Mooreville Chalk-derived breccia ranging from a differential of 100 Hounsfield units (HU) to as high as 600 HU for chalky breccia which result in subtle to abrupt breccia-matrix boundaries; (2) discernable intact burrows, which commonly are interpreted as *Planolites* but likely include some *Teichichnus* and *Thalassinoides* (along with some burrows of indeterminable genus); and (3) intact internal laminations, which abruptly terminate at clast boundaries. Rarely, *Chondrites* are observed in intact blocks and clasts but are too fine to be resolved within X-ray CT; thus, they are described by visual inspection (naked eye), particularly within a large transported block at 24 to 23 meters.

Based on stratigraphic position and lithofacies associations, four resurge units can be delineated within the 09-03 drill core (Figure 27): a *lower resurge unit* underlain by *R1* and dominated by *R2* and *R4*; a *mid-resurge unit* underlain by *R5*, dominated by *R3* and *R2*, and gradational with the overlying upper resurge unit; an *upper resurge unit* dominated by a very clast-poor, fine-grained *R2* with high-angle, chaotic lamination; and an *uppermost-resurge unit* of weathered, *R2* and possible *R5* overlain by a single occurrence of an enigmatic chalk *R6*. A

summary of the stratigraphic position of the lithofacies along with the four fundamental resurge units recognized are presented in Figure 27. The resurge units are presented in detail below in stratigraphic order of first appearance.

Figure 27. Stratigraphic column of the whole resurge interval in core 09-03. Black “tadpoles” represent planar sedimentary structures. Red tadpoles represent rotated, sub-horizontal sedimentary structures. Green “tadpoles” are clast imbrications. Red circles represent dipping structures that were originally sub-horizontal but dip direction is indeterminate or are lineation. AN is arbitrary north, and IN is inferred north; see discussion for current interpretations.

Basal shear-mixing zone (R1)

The lithofacies exhibit a lower interval of planar, well-sorted fine sands that are slightly intercalated with a muddy, glauconitic, sandy flame structure (Figure 28). The lower sands below the flame structure are sub-parallel with each other and appear to be sub-parallel with the underlying, folded, burrowed, Eutaw clay interbedded with sands. Moreover, the laminated, fine-grained sands that underlie the flame structure have alternating light and dark bands that have not been observed in either the underlying Eutaw-Tuscaloosa megablock or in the outcrop area within or near the Wetumpka impact structure. Finally, a subtle, erosional surface can be observed directly beneath the flame structure (see Figure 28). This flame structure has mixed overlying glauconitic sand and the texturally-identical quartz sand.

Above the mixing zone with the flame structure is the cross-laminated muddy, non-calcareous, glauconitic fine sand. This interval contains a high concentration of detrital glauconite (>50%) and fines upward into a non-calcareous, massive silt. Cross-stratification is subtly visible. Within X-ray CT, cross-lamination is unambiguous and is principally unidirectional; however a small interval of reversed direction was observed in the upper part of this unit (Figure 28). Direct measurements of dip within this lithofacies show a general steepening of cross-lamination upwards. However, the base of the resurge has the highest measured dip (~43 degrees), which exceeds all other sedimentary dips of the resurge.

Figure 28. *Basal mixing-shear zone (R1).* a. Original CT slice. b. Interpreted CT slice. Note short reversal between blue lines. c. Photograph of same interval as in a and b. d. Closeup of flame structure located in lower part of core segment in c. Note subtle erosional surface (upper black arrow), and below that surface shearing and elongation in a limonite nodule (lower black arrow). Also, in this instance, flame structure was not rotated for CT scan to have dipping direction parallel with slices.

Matrix-dominated breccia (R2)

This is a glauconitic, calcareous, and fossiliferous shale or mudstone that is sandy in places with weakly-expressed inclined laminations, “swirled” fabrics, sparse and pebble-sized breccia, and possible boudinage-format thick laminae of contrasting densities; possible pinching of laminae is apparent and interpreted to be evidence for boundinage. This is the dominant lithofacies of the resurge unit, occurring between other lithofacies from the base of the resurge interval to the base of *R6*.

Entrained breccia clasts include marl and chalk rip-up clasts, diverse fossil detritus, and small, thin lignitic fragments (<5cm). Fossil clasts include predominately angular, bivalve fragments of typically thin-walled bivalves, *Inoceramus* prisms, rare vertebrate fossils of shark and other vertebrate teeth, and coarse-sand-sized bone fragments. For the *R2* lithofacies, the frequency of clasts is greater within the lower resurge interval, and the upper resurge is considerably clast-poor. Above a chaotically disturbed interval within the upper resurge, the *R2* breccia is considerably clast-poor and fine-grained (silt); therefore, this interval is best described as a marly shale rather than a true breccia. On the other hand, within the marly interval, oxidation and greater calcite composition has rendered less definition within CT despite lowering the input energy (keV). Thus, mineralogically similar clasts could go unnoticed.

Petrologically, breccia matrix is either a silty-sandy calcareous mudstone or a marly, quartz wacke. In either case, the sand fraction is moderately-sorted, angular to sub-round, fine-grained, and dispersed within a calcareous matrix, within thin-section petrography (Figure 29). Possible very weak-lamination owing to possible alignment of sand grains within thin-section petrography (Figure 29) also occurs. Frambroidial pyrite is common, observable within fig.m as round opaque grains. Also a slightly elevated feldspathic content of both plagioclase and potassium feldspar is visible, assuming original Mooreville Chalk is exceptionally feldspar poor.

a

b

Figure 29. Petrography of resurge matrix and transported Mooreville Chalk clast. a. Resurge matrix. The resurge matrix is a calcareous, sandy mudstone or calcareous, quartz wacke. Note the disseminated spatial arrangement of framework grains and the overall bimodal grain size distribution. b. Transported Mooreville Chalk clast. Note the sandy and chalky appearance along with prolific, globular and bi-serial forams. Both photomicrographs were made with plane light in order to show better the fabric and grain-size.

The matrix fabrics of *R2* contrast with *transported Mooreville Chalk (R4)*. The bioturbated fabric of intact Mooreville Chalk marls and chalks is weakly-bedded or massive to “churned” bioturbated fabrics with intact burrows in some places, principally visible in x-ray CT and in some places with conventional visual inspection. Resurge-derived matrix, on the other hand, exhibits very-weakly laminated to “swirled” to “ wispy” subtle fabrics (see Figure 31 and 32, respectively), discernable within X-ray computed tomography.

Within x-ray CT, laminations of the laminated *R2* matrixes are very subtle and grade into homogeneity. With the greater X-ray CT definition of shorter core intervals, they become more prominent and easily discerned (Figure 30). Matrix laminations can exhibit relatively darker or lighter attenuation values as opposed to general matrix attenuations values. These dark and light contrasts are assumed to reflect changes in matrix density or porosity. Typically, matrix laminations are planar and parallel, but can exhibit slightly varying inclination and curvature to point where laminations appear to converge or truncate (Figure 30).

Figure 30. Inclined laminations of matrix-dominated breccia (*R2*). Subtle, inclined, planar structures (white arrows) that are typical of resurge matrix-dominated breccia (*R2*). Dashed arrow shows interpreted subtle turbulence or eddy-like structure. This Figure demonstrates that shorter core intervals reduce noise and increase definition.

Within static images, matrix lamination can be confused easily with common, post-depositional fractures of indeterminate specific origin. Occasionally, these fractures are visible as high attenuation laminae. However utilizing conjugate slices reveals both the irregular shape and a cross-cutting of primary fabrics. Thus, moving through CT slices with each core, these fractures are easily differentiated.

From 16.8 m to 14 m depth within the upper *lower resurge*, matrix fabrics-visible within X-ray CT include both weak planar lamination and “swirled” fabrics which resemble turbulent structures and contain faint, concentric laminations (Figure 31). Superficially, these eddy-like structures resemble *Planolites* burrows; however, they can be distinguished from cylindrical burrows based on the internal concentric lamination, more irregular, flattened ovoid-shape, consistently darker grayscale values, and sub-parallel long axis of multiple eddies. In contrast, *Planolites* tend to be more variable in long-axis direction, lack internal structure, smooth ovoid-cross-sections, and can be either lighter or darker than surrounding marl and chalk due to varying calcite content.

Intercalated with “swirled” fabrics, are irregular, “wispy” laminated fabrics of enigmatic structure and origin (Figure 32). These fabrics can be found rarely in other parts of the 09-03 resurge interval, but are most prevalent from 14 m depth to the base of the *mid-resurge unit* and the basal *clast-dominated breccia unit (R3)*.

Figure 31. Conjugate slices of swirled, turbulent *R2* fabric. Swirled fabrics are characterized by flattened-ovoid swirls with internal, subtle concentric laminations and somewhat irregular shapes as opposed to regularly shaped features like *Planolites*. Swirled fabric (white arrows, center slice) can be followed through conjugate slices. Red arrow marks a slightly-mineralized fracture, distinguished by cross-cutting of matrix fabric. Planar, subtle laminations can be observed at base.

Figure 32. Wispy fabric of *R2* lithofacies, uppermost *lower-resurge*. Wispy fabrics are undulating, irregular, sheet-like structures (white arrows). A few interpreted turbulent features can be seen intercalated in middle of core sections (red arrow).

Overall, this lithofacies is less common than *R2*, and although could be, in some instances, be a fully disaggregated *R4*, this facies is prevalent within the middle of the resurge unit. It is characterized as a normally graded unit of breccia that transitions from clast-supported to matrix-supported. Maximum thickness is 0.8 to 1.0 m with apparent imbrications within one interval and probable imbrications within another.

This lithofacies is most prevalent within the *mid-resurge* interval where clasts are composed of chalk and marl. Within the *mid-resurge*, there are three principal intervals of this lithofacies within the *mid-resurge*. The first interval of this lithofacies is a poly lithic clast-supported breccias of marl and chalk, which is moderately graded and transitions upward into matrix-supported breccia. Moreover, the lowermost 10 cm *R3*, as seen in Figure 33, is more

matrix-rich and contrasts with both the overlying clast-supported breccia and the underlying R2 and *lower-resurge*. At the *lower-resurge* and *mid-resurge* contact, there is a visible density/attenuation contrast with presumably lower density and/or high clay-content directly below this contact. Consequently, there is visible within X-ray CT a subtle irregular, undulatory surface that is interpreted to be subtle load clasts (Figure 33). Finally, at this *lower-mid resurge* contact, there is mud injection of overlying dark muds into underlying fractures of a main planar, tabular dike along with arcuate, concave-up thin mud-injected fractures (Figure 33).

The basal unit of this lithofacies within the *mid-resurge* is somewhat variable in its apparent imbrications and could be alternating or reversed; however, the second *R3 interval*, shown in Figure 34 is less ambiguous in clast imbrication and is more graded than the underlying similar lithofacies unit. Observations within X-ray CT show strong imbrications of well-defined polythitic clasts that grade upward into a “popcorn” CT texture that is interpreted to be small pebble-sized marl and chalky marl breccia-conglomerate (see interpretation in Figure 33). Also, unlike the lowermost interval of *R3*, imbrications are more strongly uni-directional. The second *R3 interval* is directly overlain by an *R5* lithofacies.

Figure 33. *Lower-resurge* and *mid-resurge* contact. This Figure depicts the densely injected-fractures at this contact (yellow arrow). Fractures are shown in left image and have been enhanced with the contrast and “smart sharpen” functions of Adobe Photoshop for ease of viewing. Curiously, fractures do not show well in CT scans. However, a subtle, irregular surface can be observed at contact and, with horizontal slices in borehole-down view, this surface is interpreted as being composed of load clasts (red line). Note how injected-clayey marl is similar in grayscale shade to overlying muds.

Figure 34. Imbricated *clast-dominated breccia* (R3) from the middle part of *resurge*. Original CT slice (left) and interpreted CT slice (right). Yellow-green outline marks chalky clasts. Blue outline marks marly or mud clasts. Red outline marks post-depositional clayey injection features.

For both the first and second breccia interval, the breccia tend to be sub-angular in shape; however, more clay-rich breccia (low attenuation values) tends to be rounded in shape. Some internal lamination can also be observed within larger clasts. Clast sizes can occasionally exceed the confines of the drill-core (lithofacies *R4*) and range from <1 cm to 4.25 cm.

The upper-most *R3* interval of the mid-resurge lithofacies (9.0 to 9.1 m depth) is less-defined within CT slices than underlying examples of this lithofacies. Contrasts between clasts and matrix are subtle and could represent a more homogeneous clast composition without apparent imbrications.

Finally, an example of this lithofacies is found within the *uppermost-resurge* at 3.8 meters depth. This particular interval has sub-rounded chalky clasts and grades upward into possibly semi-intact *R4* lithofacies and likely is, in part, brecciation of chalky *R4*. Rounded chalky clasts at the base suggest transport. Although some features are reasonably defined, oxidation and weathering near the surface formed this lithofacies, making uppermost-resurge challenging to interpret. Nevertheless, from the better defined lowermost meter interval, this stratigraphic section is believed to be lithofacies *R3* and *R4*.

Transported Mooreville Chalk (R4)

Where clast size exceeds the confines of the drill-core in the horizontal dimension, clasts are recognized as boulders. Such clasts are interpreted based on intact internal bedding, trace fossils, and other primary sedimentary structures (Figure 35 and 36). Boulders range from a minimum size of 0.065 m to a maximum stratigraphic size of 1.0 m. Predominately, most intervals of *R4* are found within the *lower-resurge*, which can be seen in Figure 27. Orientations of boulders are similarly aligned with matrix inclination trends but can diverge locally.

Figure 35. Bioturbated example of an *R4* interval. Red lines mark clast boundaries and there is *in situ* brecciation above. White arrows mark typical examples of *Planolites*, which are located within semi-intact transported Mooreville chalk. This interval is an example of a rare lower-resurge polyolithic-laminated lithofacies (*R5*).

Figure 36. Brecciated top of *R4* lithofacies. Left slice is original CT slice. Right CT slice is interpreted where in the red lines delineate *in situ* brecciation.

Lithology ranges from chalk to marl, which are commonly caught frozen (arrested) in the process of disaggregation and dismemberment and exhibit wide matrix-filled fractures (Figure 36). Specifically, transported boulders include fossiliferous, light-gray, sandy, phosphatic chalk with interbedded marl; green-gray, bioturbated, fossiliferous, silty marl containing *Planolites* (Figure 35), *Teichichnus*, and *Chondrites*; and heavily glauconitic, chalky sandstone-sandy chalk (Figure 37). In-situ brecciation of *R4* lithofacies within the *lower-resurge* typically fragment along block top whereas block bases are angular or sub-parallel to bedding but lack breccia in most cases (Figure 37). However, uncommon detachment of block bases can create local basal brecciation that appears to be sinking into subjacent matrix.

Figure 37. *In-situ* brecciation of *Transported Mooreville Chalk megaclasts (R4)*. Original slice (left) and interpreted slice (right), which has red lines delineating mud-injected fractures. Note sub-parallel fracturing with bedding trends and similarly aligned fractures/bedding with general dipping trends (dip angle average = 32 degrees).

Poly lithic-laminated matrix (R5)

This is an uncommon facies in which strongly-expressed laminations of contrasting and alternating lithology resemble cross-beds and cross-lamination. Cross-bedding and cross-lamination can be discerned in both X-ray CT and visual inspection. Lithofacies *R5* are less than 10 cm in thickness and, above the partially-cross-laminated *R1* lithofacies, *R5* lithofacies have been delineated at only three locations: a short interval (20.1 m depth) underlying a *R4 block* within the lower resurge; two cross-bedded and cross-laminated intervals that cap graded *R3* intervals (11.4 and 9.6 meters depth, respectively).

The lowermost example of the *R5* lithofacies has clearly visible truncation surfaces and internal lamination surfaces appear similar in inclination (Figure 35). Superjacent to this interval is a very short interval of chaotic, churned matrix overlain with a bioturbated, interbedded chalk and marl *R4* lithofacies. However, this *R5* lithofacies is penetrated by calcified tubes that in three-dimensional models built with X-ray CT multi-planar reconstruction (MPR) reveal an inclined, meandering path that cross-cut lamination.

The *mid-resurge* contains two *R5* intervals. The first of these two intervals is a trough-cross-bedded, calcareous, glauconitic sand of alternating lithology shown in Figure 37. This unit is interpreted to be trough-cross-bedding due to the shallowing-upward lamination, trough-shaped foresets, and incised trough cross-bed sets that are cut into underlying lithofacies. This unit terminates the second *R3* interval. Directly above the interval, large (4 cm) *Inoceramus* fragments are resting directly upon the last foreset with accompanying compaction features.

The second *R3* interval is finer-grained and, within both visual inspection and X-ray CT, laminae appear to be alternating marl and chalk. Unlike the lower *R5* interval, laminae are more similarly inclined with subtle internal truncation surface and are finer-grained (very fine sand to

silt-sized). Ripple-like forms within the laminae suggest oscillatory currents. Similarly, this unit has a large, interbedded chalk clast lying directly upon the last laminae. Compaction features show interpenetration from above (Figure 38).

Figure 38. *Poly lithic-matrix (R5)*. This is an example of the *R5* lithofacies that directly overlies the lithofacies within the *mid-resurge*. Lying directly on top of this lithofacies are *Inoceramus* prisms with accompanying compaction features. Within d is a photograph of trough cross-bedding. In e, is a closeup of individual trough foresets, looking up trough long axis.

Figure 38a. Conjugate slices of polyolithic–laminated matrix (R5). This is the uppermost example of this lithofacies within mid-resurge. White solid arrows show clasts (marked in b, f). There is a possible rippled surface shown with dashed arrow. Black arrow shows compaction features, which are followed from left to right to the place where they diminish with the absence of the clast. In upper part of core, there is a chalky clast with some limited *in situ* brecciation.

Enigmatic Chalk (R6)

The genetic origin of this lithofacies is enigmatic. Texturally, it is distinctive sedimentologically from underlying units and has been proposed by Ormö et al. (2010) to be a

secular deposits and suggested by Markin et al. (2011) to be an altered transported Mooreville Chalk block. This uppermost unit is a phosphatic chalk with modern diagenetic overprinting of caliche nodules. Within the X-ray CT images, the upper two meters exhibit subtle features such as internal, inclined lamination, burrows, and wide fractures. Precipitation of caliche nodules has inherited high-angle inclinations. With hand-specimen-level examination and regular-light optical microscopy, coarse-sand sized grains of bivalve fragments, black phosphate, bone fragments, and quartz clasts have been observed. Within thin-section petrography, roughly laminated oxidized glauconite can be observed and with X-ray MPR caliche nodules follow conspicuous inclination trends.

Structural Features of the Resurge

The resurge interval was examined for structural features and those were compared with structural features of the underlying Eutaw-Tuscaloosa megablock-impactite sand complex. Conjugate, systematic micro-faults were not observed within the resurge interval; however, local normal faults have been observed, which are interpreted to be compaction features. Clastic dikes and impactite sands with allochothonous textural characteristics were not observed within the resurge interval. Specifically, no injected sediments within the resurge interval appear to have been sourced from the Eutaw-Tuscaloosa megablock.

Fractures are common throughout the resurge interval and are likely either syn-depositional or post-depositional. Fractures were previously logged and reported by Ormö et al. (2010), and within that study, fracture density (e.g. fractures/meter) peaks twice at approximately at 5.0 and 13.5 meters. The peak at 13.5 meters roughly corresponds to the *lower-resurge* and *mid-resurge* boundary and many of these fractures are attributed by this author to be injected muds originating at this surface. Near the peak of 5.0 meters, fractures are discernable using X-

ray CT in the *upper* and *upper-most resurge* intervals as wide matrix-filled fractures, which do not have a clear point of origin. Furthermore, lesser occurrences of dark mud-filled fractures, similar to the fractures of the 13.5 meter peak, are present below the second *R5* occurrence. Despite their visual similarity to underlying mud-injected fractures, a point of origin for the mud-injection is uncertain.

Precise measurements of inclined laminations and clast imbrications are presented in as a “tadpole plot,” a plot of azimuth-direction dips (Figure 27), and these directional patterns are described below. These measurements were derived exclusively from X-ray CT according to methods described within X-ray CT methodology. Within the *lower-resurge*, inclination directions are similarly directed towards the arbitrary northwest; however, there is a short reversal in the upper portion of the *lower-resurge* as shown in Figure 28. Utilizing clast imbrications and inclined laminations, there are variable clast imbrications in the lowermost part, but in the strongly imbricated, second interval of *R3*, apparent current directions show a complete reversal of lower-resurge inclination orientations. Likewise, trough cross-bedding directly above show similar interpreted current directions as in the subjacent clast imbrications. Above the aforementioned trough cross-bedding, there is a near 90-degree rotation towards the arbitrary north. Above the rotated inclination directions (above eight meters depth), inclination trends again rotate counter-clockwise but transition into a nearly random pattern (or “bag of nails”) set of orientations.

Some degree of rotation for resurge interval is evident because angle of repose and inclination of features that should be horizontal. Features that should have been sub-horizontal are inclinations with indeterminate strikes or lineations that indicate rotation, for example originally sub-vertical escape structures. These features are identified in fig. a as red

circles(indeterminate strikes) and red dip-direction symbols for sub-horizontal planar features. Unfortunately, deformation along these surfaces (i.e., load clasts) or strike-less features that do not generally allow strikes to be measured within CT analysis. Features without strike include rotated, relatively straight pyritized, calcified water-escape tubes and direction of clast compaction and penetration into underlying sediments. The maximum rotation of 43 degrees occurs at the erosional base of the resurge. Above this sub-horizontal indicators tend to be shallower, for example, 20 to 32 degrees. This could indicate that rotation is syn-depositional. However, rotation of underlying megablock is likewise variable; therefore, post-depositional deformation such as faulting and/or folding could account for some of this variability. Conversely, subtle topography along stratigraphic surfaces could account for variability of the rotated resurge.

0904 Drill-core Results

Based on their preliminary results, King et al. (2010) proposed that the 09-04 well penetrated the slumped, overturned flap (herein termed overturned fold) of the southeastern portion of the crater rim. This was so interpreted because of a sequence of overturned Tuscaloosa Group and Eutaw Formation, which were underlain by crater-filling sands of mixed origin, and because of the well's proximity to the crater rim. The two-part subdivision of King et al. (2010) into overturned intact units (Figure 39) and underlying crater-filling sand (Figure 40), established a natural stratigraphic division for logging and descriptive purposes.

Figure 39. Stratigraphic column for the overturned fold section of drill core 09-04. hz=hinge zone.

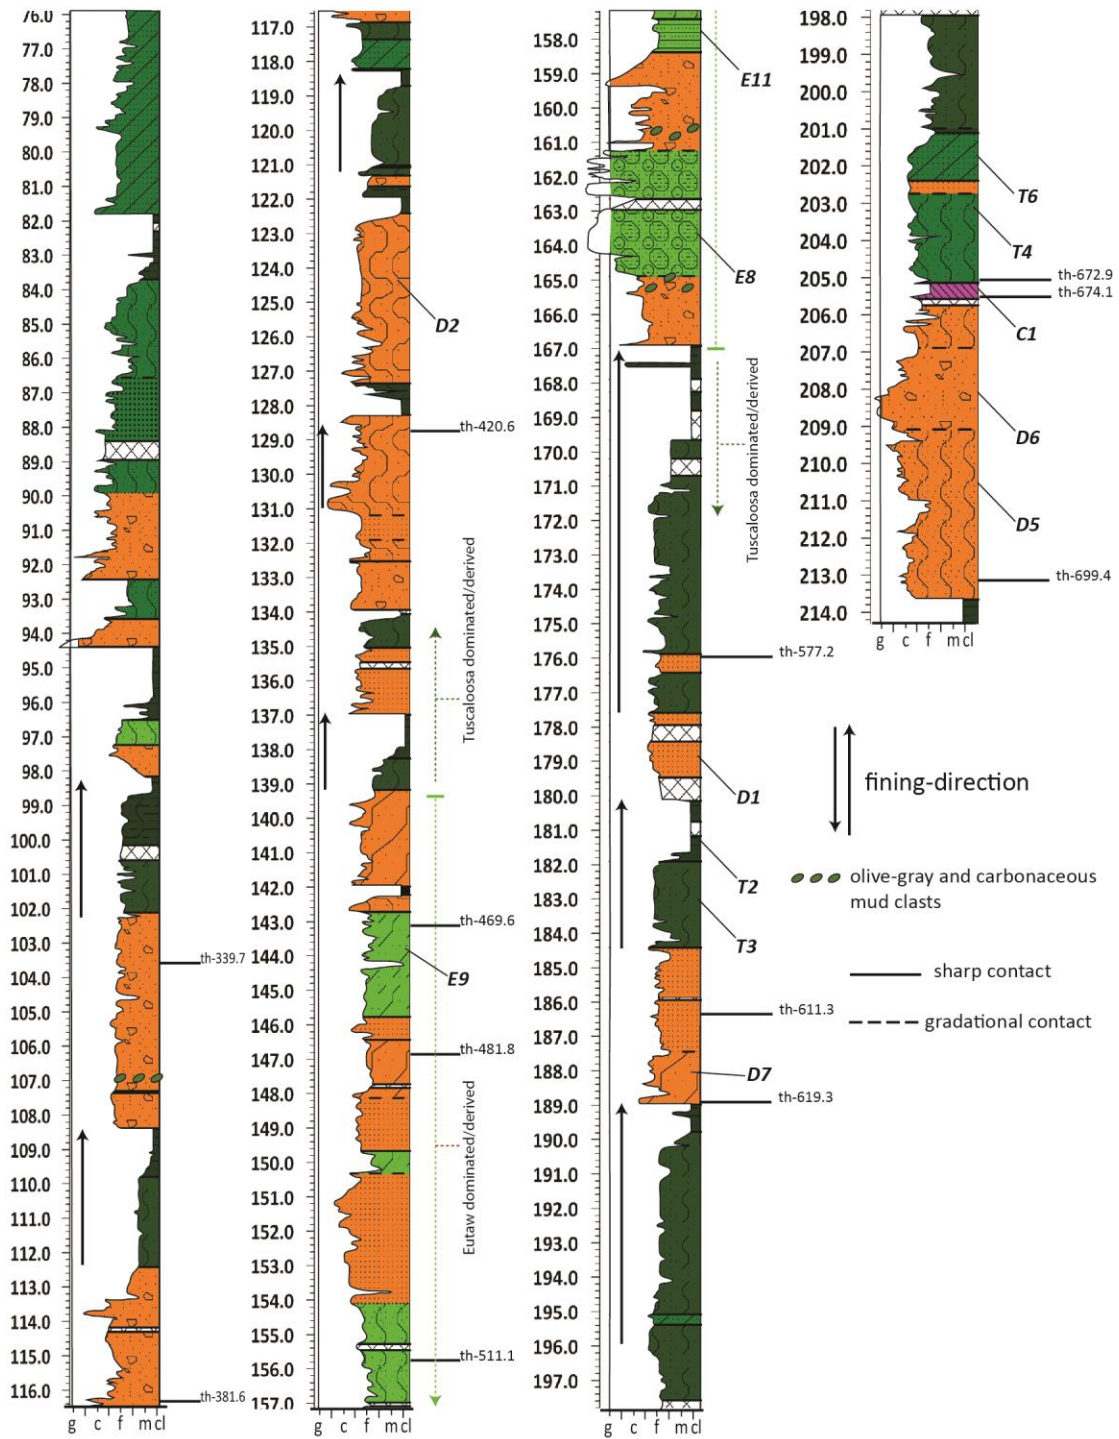

Figure 40. Stratigraphic column for lower impactite sand section of drill core 09-04. th = thin section (depth given).

The lithofacies, in non-stratigraphic order for semi-intact Tuscaloosa strata, are as follows: *Overbank/paleosol mud (T2)*; *Overbank/paleosol sand/sandstone (T3)*; *Contorted, laminated sand/sandstone (T4)*; *Fluidized sand/sandstone (T5)*; *Cross-stratified Sand/Sandstone (T6)*; *Cross-stratified, Granular-pebbly sand (T7)*; and, *Massive, Reverse-graded, Granular-pebbly Sand (T8)*. The lithofacies, in non-stratigraphic order for semi-intact Eutaw Formation strata, are the following: *fluidized sand/sandstone(E4)*; *contorted, laminated sand/sandstone(E7)*; *grayish-green to green-black, mud conglomerate (E8)*; *disrupted Sand (E9)*, *interstratified, micaceous, lignitic mud and sand (E10)*; *rhythmic laminated lignite and sand (E11)*; *cross-laminated sand (E12)*; *olive-gray, fossiliferous, clayshale (E13)*; *carbonaceous shale (E14)*; and *sandy lignite (E15)*.

The lithofacies, in non-stratigraphic order for disaggregated, impactite sands, are the following: *massive, structureless, impactite sand/sandstone (D1)*; *fluidized impactite sand and sandstone (D2)*; *contorted, impactite sand/sandstone (D5)*; *massive, structureless, granular-pebbly impactite sand/sandstone (D6)*; and *inclined, poorly-moderately stratified impactite sands/sandstone (D7)*. Crystalline lithofacies are a rare occurrence within 09-04, present only within the lowermost 30 meters. Only one crystalline lithofacies is confidently identified within 09-04: *saprolitized Metamorphic Rock (C1)*. All preceding lithofacies are described and characterized below for stratigraphic order of appearance for the first listed lithofacies.

09-04 Lithofacies Description and Characterization

Overbank/paleosol mud (T2), *Overbank/paleosol sand/sandstone (T3)*

The Overbank/paleosol mud (*T2*) and Overbank/paleosol sand lithofacies (*T3*) are distinctive intervals of the Tuscaloosa Group. Although the designation of Overbank/paleosol is, in part, a genetic one rather than descriptive, the sedimentary features of these delineated intervals are unambiguous and unique to these lithofacies. Within the 09-04 core, both the *T2*

and *T3* lithofacies are defined by the fossil combined features: pervasive bioturbation with rootlets and a terrestrial organism (forming the ichnogenus, *Taenidium*); oxidized appearance due to mottled red, purple, orange, and yellow due to iron oxides; presence of clayey plinthite nodules within paleosols; and massive character. *T2* lithofacies are gradational with *T3* lithofacies. Also, relict lamination and/or cross-stratification can be observed within sandy intervals of *T3*.

Aside from rootlets, ichnofossils of both *T2* and *T3* are exclusively of the ichnogenus *Taenidium*. These ichnofossils are one to two cm wide, commonly interpenetrating, somewhat meandering burrows with meniscate backstuffing that are horizontal, vertical or oblique to the vertical or horizontal plane (depicted in Figure 41d). Previously, these burrows have been described and designated as *Taenidium* by Savrda et al. (2000) from outcrop exposures in Tuscaloosa Group overbank deposits within eastern Alabama. For the Wetumpka impact crater, Johnson (2007) identified these burrows as belonging to *Taenidium* within Tuscaloosa mudstone facies of the Shroeder-1 and Reeves-1 wells (core holes 98-01 and 98-02, respectively), located within megabreccia near the center of the crater.

Figure 41. Selected 09-04 examples of Semi-intact Tuscaloosa lithofacies a. *T2-D1 contact*. Note reduced gray clay near impactite structureless sands. Also, not *T2* clasts within *D1* volume. B, c. Undulose contact and parasitic folds along contrasting lithologic contact. d. Example of *Taenidium* (insect burrows), diagnostic for Tuscaloosa. e. Cross-stratified Sand and moderately-reduced *T2* lithofacies. f. Brecciated *T3* lithofacies. Breccia edges marked lightly with pencil. Breccia matrix is light gray sand at base.

Mottled coloration of red, red-purple, orange, and yellow transition to light and medium grays are interpreted to be reduction of iron-oxide staining of these facies. Within *T2* lithofacies, areas of reduction are adjacent to zones of permeable sand (Figure 38a). *T2* and Tuscaloosa semi-intact cross-stratified sand contacts are 0.5 to 43 cm in length whereas reduction areas adjacent to impactite structureless sands beneath the overturned fold are up to 2 meters in length. Reduction areas transition gradually from the original oxidized colors to grays. However, in both semi-intact *T2* intervals within the overturned fold and *T2* boulders and blocks, irregular injected-sands along with pre-existing fractures have abrupt transitions from the pre-existing red to orange colors of oxidation to light gray colors of reduction. This can create mottled appearance in both instances.

Within intervals of reduction, *T2* lithofacies commonly exhibit marginal to strong effervescence (as defined in the methodology section). Semi-quantitative estimates of calcium carbonate content are presented in Figure 39. Typically, calcium carbonate content is interpreted to be higher within the upper extent of *T2* blocks and diminishes with depth which can be seen in Figure 39. However, some intervals show either a parabolic trend (Figure 39b) or ambiguous, irregular trends. The presence of carbonate within clayey *T2* lithofacies is always associated with areas of reduction (yellow-gray to gray clays) and is not associated with areas without reduction (red, red-purple, or red-orange).

In contrast to *T2*, lithofacies are commonly substantially reduced, possibly due to greater permeability. Within the lowermost 30 m of the 09-04 well, the thoroughly bioturbated, massive intervals of *T3* are difficult to distinguish from better-sorted structureless impactite sands. Where some relict ichnofossils remain (i.e., rootlets or *Taenidium*), these intervals of mottled oxidation are delineated as *T3*.

Finally, intensive bioturbation within *T2* intervals removes planar features that may indicate clast or bedding inclination. Along contrasting lithologies of clayey *T2* intervals and intervals of cross-stratified sands, graded, massive sands, and impactite sands, the contact is strongly to moderately undulating showing small-scale parasitic folds across these interfaces (Figure 41 b, c).

Figure 42. Contorted and fluidized lithofacies *T2* in core 09-04. Blue highlights contorted parts. Red tick at lower right is at 693 feet in well 09-04.

Figure 43. Effervescence log for wells 09-04. This a bar graph showing observations for the strength of effervescence (as described in methodology) for 0.4 ft (12 cm) intervals. Lower panel a shows a typical, decreasing-effervescence subset trend with increasing depth. Lower panel b shows a typical, subset parabolic-trend with increasing then decreasing trend. Two overarching decreasing trends are show in top panel directly above a and b.

contorted, impactite sand/sandstone (D5); contorted, laminated sand/sandstone (T4, E7); fluidized sand/sandstone (E4/T5); and fluidized impactite sand/sandstone (D2).

All well 09-04 lithofacies of *contorted, impactite sand/sandstone (D5); contorted, laminated sand/sandstone (E7/ T4); fluidized sand/sandstone (E4/T5); and fluidized impactite sand/sandstone (D2)* are delineated based upon ductile structural deformation in which primary sedimentary structural features (i.e., cross-lamination, cross-bedding, and reactivation surfaces)

did not previously exist (fully-disaggregated sediment) or have been obliterated or deformed to the point of being too ambiguous to identify. All of these lithofacies are distinguished based on the type of folding and whether original textural characteristics remain or sediment texture is derived from complete disaggregation of target sediment (i.e., mega-breccia matrix).

Lithofacies *D5* intervals and *E7/T4* intervals, owing to Eutaw and Tuscaloosa respectively, are a series of stacked recumbent to highly inclined folds in which inflection points of opposing limbs appear to be 0.1 to 1.0 meter apart. Generally, fold aspect ratio is wide to broad, and fold tightness is gentle within wide folds and grades to close with increasing tightness of folds (see nomenclature definition in Twiss and Moores, 2007). An example of the structural style of these lithofacies is shown in Figure 43. Although ductile deformation is similar for *D5*, *E7* and *T4*, textural characteristics are diverse dependent upon which of the three contorted lithofacies are observed.

Figure 44. Contorted and Fluidized lithofacies of well 09-04.

Figure 45. Mica deformation structures and petrographic features of impactite sands within drill core 09-04. Top panel (ppl) shows kinked micas. Lower panel (xpl) shows devitrified interstitial glass (black arrow) with cherty appearance and somewhat upward oriented altered muscovites and chloritized biotite (low birefringence, anomalously blue colors).

Within *D5* intervals, folds are defined by subtle oxidized bands and/or subtle laminae composed of alternating, contrasting grain-sizes as depicted in Figure 43. Thin-section petrography at 699.4 ft (213.2 m) depth within an interval of *D5* show contorted and kinked mica books along with some random mica orientations and muscovite wrapped about quartz, quartzite, and feldspar clasts. These mica deformations are depicted within Figure 44. Matrix includes fine, altered, chloritized micas and possible devitrified glasses altered to interstitial cherts and framework grains have diverse roundness from sub-round to very angular. Although the *D5* intervals are not assigned to specific Eutaw or Tuscaloosa origin, shear, disaggregation, and remobilization of sediment could have altered the sediment of these intervals from an original Tuscaloosa or Eutaw origin.

Where contorted intervals are interpreted as Eutaw, *E7* lithofacies, thin ≤ 1 mm, lignitic and micaceous laminae are associated with a gray, moderately to well-sorted, medium to fine-grained texture. Fold geometries are defined by lignitic and/or micaceous laminae. This lithofacies is mostly found within the Eutaw-dominated block/boulder interval.

Where contorted intervals are interpreted as Tuscaloosa, *T4* lithofacies, micaceous, oxidized, moderate red to pale yellowish orange or light gray, and gravelly cross-strata are observed which are sufficiently deformed to make foreset geometry ambiguous. Therefore, with these seemingly textural similarities with Tuscaloosa, these intervals are interpreted to be contorted intervals of Tuscaloosa cross-stratified channel sands. Fold geometry resembles *D5* and *E7* intervals and is defined by the ductile-deformed cross-strata.

Fluidized sand and sandstone (E4/T5) and *fluidized impactite sand and sandstone (D2)* are similar to contorted lithofacies and are likely transitional with the aforementioned lithofacies; however, fluidized intervals are set apart due to their more severe ductile deformation. Where

contorted intervals have gentle to close fold tightness, fluidized intervals have obtuse fold tightness of fan to involute, folding angles from 181 degrees to greater than 250 degrees, respectively. The more involuted folding manifest as eddy-like structures defined by iron-oxide stained bands. Other ductile structures include pinching of folds and undulose bulls-eye patterns about rotated clasts (Figure 43). Lithofacies *D2* intervals have better defined folds due to distinctive, contrasting mineral staining of light grays, moderate reds, various oranges and yellows. However, fluidized intervals attributed to Eutaw or Tuscaloosa have clear proximity and textural affinity with adjacent, semi-intact intervals of Eutaw and Tuscaloosa strata. In addition, folding and ductile deformation have much smaller scales with opposing limbs less than 10 cm apart and are convoluted and are polyclinal with folding defined by subtle coloration and textural variation. Structurally these intervals reveal fluidized intervals of drill core 09-03. Finally, in contrast with overbank lithofacies, fluidized impactite sands which are calcareous are commonly also heavily oxidized with iron-oxide staining of moderate to orange-reds.

Although interstitial, devitrified glasses are somewhat common, particularly with depth, one thin section at 420.6 ft (128.2 m) depth has one instance of a framework, medium sand-sized impactite glass (Figure 45). This particular grain is only slightly devitrified to quartz and possibly had a more globular shape before compaction-derived deformation. As revealed by thin-section petrography, accessory minerals of this location include hornblende, garnet, kyanite, zircon, and euhedral to anhedral clinopyroxene. Framework grain mineralogy is predominately quartz at 92.0% and a minor feldspar fraction at 7.5 % of mostly potassium feldspar. Within this thin-section, fluidized impactite sands reveal a substantive clayey matrix fraction at 29.0%, but a very low porosity at 0.3%. Thusly, the fluidized sands are a quartz wacke of low porosity. Texturally, the fluidized impactite sand resembles structureless intervals (*D1*) detailed below.

Figure 46. Example of impactite glass within drill-core 09-04, specifically thin-section sample 0904_481.8. Note deformation by compaction and intrusion by framework grains. Plane light (top). Crossed polars (bottom).

Massive, structureless, granular-pebbly impactite sand/sandstone (D6); Massive, structureless, impactite sand/sandstone (D1); Inclined, poorly-moderately stratified impactite sands/sandstone (D7)

Based upon hand lens and thin-section petrographic observations, *D6* and *D1* lithofacies are massive, structureless intervals of light to dark gray, poorly to very poorly-sorted, unconsolidated to poorly-lithified, micaceous, generally angular to sub-angular, mostly matrix-supported, medium to coarse-grained clayey sand or sandstone with a minor, diverse mineralogical, accessory assemblage. Utilizing thin-section petrographic point counts of framework grains (quartz, feldspar and lithic grains), quartz ranges from 71.2% to 93.6% with a mean of 87.6%; feldspar ranges from 6.4% to 28.7% with a mean of 12.3 % and is dominantly potassium feldspar; and lithic fragments are a rare, accessory component which, aside from polycrystalline quartz clasts (i.e., quartzites), are composed of micaceous schists, and, gneissic fragments. Matrix volumetric proportion ranges from 11.5% to 28.9% with a mean of 20.1%. Thus, with the petrologic scheme of Carozzi, (1993), *D1* and *D6* are generally composed of marginally-subfeldspathic wackes. All point count data for drill core 09-04 are presented in the Appendix.

Using the standard point-counting method, heavy and accessory minerals are rarely counted on point count grids, but all visible mineral phases are nevertheless noted. Typically, only garnets or kyanite have been included in point counts. However, each thin-section reveal diverse accessory minerals which could include shattered euhedral garnets, heavily-fractured kyanite grains, common detrital and euhedral zircon, common anhedral, rounded epidote-zoisite, clinzoisite, uncommon sphene fragments, uncommon green amphiboles, uncommon clinopyroxene, and rare instances of partially-altered, oxidized olivine, orthopyroxene, and silt-

sized staurolite grains. Accessory minerals mentioned above appear to be more diverse within thin-sections 0904-339.7 and 381.6, directly below the overturned fold. However, commonly within *D6* and *D1* intervals, clusters and isolated, pink-red fragments of garnets may be observed with a hands lens. A garnet cluster has been observed within thin-section 0904-470 that has shattered, high-relief, isotropic, possible dodecahedron habit, and some quartz and mica inclusions; however, one possible garnet that is associated with this cluster has light gray-yellow birefringence (Figure 47).

Matrix composition is generally a finely-grained chlorite-micaceous mud, iron-stained clayey mud, or sporadic, devitrified glassy-micaceous mud matrix. The matrix fabric was revealed by either ubiquitous micas, which have an entirely random appearance, upward lineations, or swirled, flowing fabric. Within this lithofacies, matrix and, uncommonly, framework grain mineralogy have commonly-altered, chloritized biotite, clay-replaced muscovite, and replaced chloritized plagioclases with relict twinning (Figure 47). Micas within matrix commonly have gray birefringence to blue anomalous colors within crossed-polars. Some muscovite book-like crystals show possible chloritization along some edges and alteration to clays. Conversely, some mica book-like crystals are replaced by clay pseudomorphs that are, in turn, appear to be partially chloritized, evident with green coloration in plane light and anomalous birefringence colors. Matrix micas range from random orientations to upward, vertical alignments with wrapping, kinking of micas about framework grains. In addition, directly below the overturned fold, within thin-section 0904-339.7, muscovite grains show swirling geometries from a green-gray, massive structureless interval (Figure 48).

Figure 47. Example of shattered, euhedral garnets with associated heavy minerals. Top panel is in cross polars. Bottom panel is in plane light. Garnet (g), anomalous, low birefringence garnet (ag), plagioclase (pl), and sphene (sp) are labeled.

Figure 48. Swirled fabric at overturned fold/lower megabreccia contact, drill core 09-04. Note swirled T3.

Aside from the aforementioned sedimentological characteristics, massive, structureless sands contain sporadic clasts including isolated lignite, cobble-sized medium gray overbank mud clasts, admixed sub-rounded quartzite pebbles and coarse sands of probable Tuscaloosa origin. Further, this sand is gradational with other sandy lithofacies. In the instance of *T2* lithofacies and impactite sand interactions, contacts are either sharp or possibly brecciated. Where structureless impactite sand intervals are granular-pebbly, larger clasts appear to have random orientations, appear to be graded, and are widely dispersed; *D6* lithofacies resemble sedimentological characteristics of Exmore breccia of the Chesapeake Bay impact crater (cf. Figures 7 and 8 in Horton et al., 2008)

Finally, although mostly structureless, locally inclined laminations, swirled convoluted laminations also occur. Where these poorly-moderately expressed inclinations occur, they are delineated as *Inclined, poorly-moderately stratified impactite sands/sandstone (D7)*. Upon examination, these poorly-expressed laminae lack unambiguous primary sedimentary structures of target sedimentary strata and do not exhibit unambiguous folding and contortions as observed within ductile-deformed lithofacies. However, it is possible these are folding of impactite sands beyond a scale discernable within this drill-core.

Saprolitized Metamorphic Rock (C1)

The C1 lithofacies is delineated only at one location. This interval is a strongly-weathered, lithified, micaceous, quartzose schist in which muscovite and biotite has altered to vermiculite; due to the high quartz and feldspar volumetric content, 76%, an alternate interpretation could be a schistose quartzite. Petrographically, this lithofacies shows interstitial glass that have devitrified to cherts. Also, devitrified glasses show penetration by framework grains, suggesting *in situ* melting. Moreover, devitrified glasses have been suggested to be

checkerboard feldspars (R. S. Harris, personal communication, 2010). It may be that the pervasive weathering and alteration of this interval are, in fact, resulting from a pre-impact interval of saprolite rather than crystalline ejecta fallback or avalanche-entrained crystalline ejecta.

Cross-stratified Sand/Sandstone (T6); Cross-stratified, Granular-pebbly sand (T7); Massive, Reverse-graded, Granular-pebbly Sand (T8)

T6 and *T7* lithofacies are light gray to heavily oxidized orange-yellow, micaceous, sub-angular to sub-round, clast to matrix-supported, cross-stratified medium to very coarse-grained sands that are interpreted to be fluvial channel sands of the Tuscaloosa group. Similarly to descriptions by Reinhardt et al. of equivalent Tuscaloosa channel sand complexes, these intervals reliably fine towards lithofacies *T3* where pedological development is overprinted upon cross-stratified sands and ultimately grade into clayey *T4* lithofacies paleosols. Foreset boundaries and internal cross-lamination are defined by iron-oxide oxidation and/or grain-size changes. Bioturbation is wholly absent except in areas that transition into *T2* and *T3* lithofacies where *Taenidium* are common. *T7* intervals differ from *T6* intervals only due to laminae and dispersed quartzite pebbles and granules along with a basal, thin conglomerate.

Massive, Reverse-graded, Granular-pebbly Sand (T8) intervals, restricted to the uppermost 50 meters, are interpreted to be partly fluidized *T7* and *T6* intervals. Texturally, *T8* intervals are identical to *T7* and *T6*; however, individual foresets are indiscernible possibly due to sediment remobilization. Along *T2* and *T8* lithofacies contacts in the uppermost 20 meters, contrasting lithofacies have irregular, undulose surfaces. Generally, grain-size fines downward as to be expected if channel sands are overturned. However, within one *T8* interval, there is an

anomalous conglomerate at the base along a *T2/T8* undulose contact that based on geometry of this contact suggests third-order folding.

Grayish-green to Green-black, mud conglomerate (E8)

This block is a Grayish-green to Green-black, sub-rounded to well-rounded, very poorly sorted mud conglomerate with a medium to dark gray, moderately to poorly-sorted, carbonaceous, medium to coarse-grained sand matrix. Located near the center of the lower breccia interval, this block interval is interpreted to be a basal channel deposit of the Eutaw Formation due to the presence of texturally identical mud clasts present within the Eutaw Formation at 54, 72, and 78 m depth. Moreover, similar mud clasts within the overturned fold appear to be either constrained as a 0.3-m thick unit or a lag of some kind, whereas the *E8* lithofacies has a 4-m stratigraphic thickness. Nonetheless, mud rip-ups and clasts similar to the *E8* lithofacies are restricted to the Eutaw Formation within the overturned fold. Where the *E8* lithofacies comes in contact with *D6* lithofacies, dispersed mud conglomerate exist along contact zones and intermixed within stratigraphically adjacent structureless impactite sand intervals.

Disrupted Sand (E9); Interstratified, Micaceous, Lignitic-mud and Sand (E10); Rhythmic-laminated lignite and sand (E11); Cross-laminated Sand (E12)

E10, *E11* and *E12* lithofacies are texturally-related Eutaw Formation lithofacies and *E9* lithofacies is a structurally disrupted block of possibly *E10* and *E11* lithofacies. Rhythmic, laminated lignite and sand (*E11*) lithofacies is an interval within the overturned fold of rhythmites (see definition from Davis, 1983) composed of alternating lamination lignitic muds and micaceous, fine to medium-grained, moderately to well-sorted, sub-rounded, quartzose sand. *E10* lithofacies is texturally identical to *E10* but internal stratigraphic units of *E10* are very thin to thin beds rather than laminae. Moreover, *E10* lithofacies are transitional with *E11* lithofacies

where laminae grade to thin bedding and can include cross-lamination within sandy stratigraphic units. *E12* lithofacies are, in turn, gradational with *E10* lithofacies. *E10* lithofacies are light gray to medium gray, cross-laminated or cross-bedded in parts, moderately-sorted, sub-rounded, medium-grained to basally coarse-graded which lacks lignitic laminae.

Based upon observations from smear slides, ichnofossils, and hand lens, lithofacies *E10*, *E11* and *E12* are interpreted to be marginal marine based on the following observations. Within lithofacies *E10* and *E11*, smear slides within lithofacies *E10* and *E11* show sparse glauconitic grains and a feldspathic proportion <10% which, unlike petrography of lower impactite sands, appear to have similar proportions of plagioclase and potassium feldspar. Within some laminae, lignite fragments and lignitic, very thin bedding reveal *Teredolites* borings, a typically marine ichnofacies of “sparse to profuse, club-shaped borings” within woodgrounds (Pemberton, et al., 2004) or sediment-starved “log-grounds” of Savrda and King (1991). Although muscovite is the dominant mica overall, some laminae are nearly exclusively biotite whereas Eutaw lithofacies of 09-03 are comparatively, exclusively muscovite or white micas. Rythmites within marginal marine settings, evidenced by both the presence of both glauconite and lignite, suggest a tidal setting, possibly tidal flats within a back-barrier setting (Davis, 1983).

Disrupted Sand (*E9*) is a disturbed, possibly sheared block of *E10* or *E11* lithofacies within roughly the middle of the lower megabreccia at 142.8 to 145.8 m depth. Lignite laminae range from convoluted lamination to discontinuous fragments that are possibly formed as boundinage features. The lignite to sand ratio (visible in suggests that this disrupted interval was originally an *E10* interval. However, matrix sand between lignitic fragments and lamination is a dark gray so lignite could be admixed into interstratified sands. This interval also contains dispersed coarse-sized quart clasts and slight yellow-oxidation within this interval. An example

of this lithofacies is shown in Figure 49. Furthermore, sporadic, devitrified glass that resemble flow structures are found within the upper part of this lithofacies (Figure 49). This could indicate that glassy matrix has been entrained within this sheared megabreccia block.

Olive-gray, Fossiliferous, Clayshale (E13); Carbonaceous Shale (E14); and Sandy Lignite (E15)

E13, E14, and E15 lithofacies are observed within the overturned fold and only *E15* lithofacies are found within the underlying megabreccia. At 58.2 and 59.6 m depth, lithofacies couplets of *E13* and *E15* are delineated. *E13* is a fossiliferous, Olive-gray, clayshale with some scaly fabric possibly derived from shear of this clayshale along with lamination. Along laminated planes, macerated plant carbon films are observed. In the higher 58.2 m interval, the *E13* lithofacies abruptly transition to *E14* lithofacies. *E14* lithofacies is a fissile carbonaceous silt to lignite interval with reported amber grains in the field. However, the underlying 59.6 m interval is stratigraphically reversed as compared to the 58.2 meter interval with the *E14* lithofacies abruptly transitioning into *E13* lithofacies. *Sandy Lignite (E15)* lithofacies are black lignite intervals with intrusions of medium sands and inclusion of amber grains. Aside from isolated lignitic clasts and laminae, logged lignitic intervals of *E15* lithofacies are found within the lower megabreccia interstratified intervals within two semi-intact deformed intervals (Figure 50).

General Stratigraphic, Sedimentological, and Structural Characteristics of the Drill-core

09-04

Visual estimates of modal grain-size and maximum grain-size for the overturned fold and lower impactite sands, logged inclination of planar structures and faults, and logged lithofacies for the overturned fold and lower impactite sands are presented in Figures 52, 53, and 54, respectively. For reference, logged lithofacies for the overturned fold and lower impactite sands were presented previously in Figures 39 and 40, respectively. Following detailed examination and logging of the overturned fold, presented in Figure 39, thicknesses differ from preliminary results of King et al. (2010). Within the present study, overturned Tuscaloosa is measured at 51.0 meters thickness. At the hinge zone, Eutaw formation is estimated at 30.5 meters thick. The upright Tuscaloosa at the base of fold is estimated at 20.5 meters. Discrepancies with previous preliminary reported thicknesses of upper Tuscaloosa, Eutaw, and lower Tuscaloosa, 38, 18, and 27 meters respectively, are due to ambiguities with the Tuscaloosa-Eutaw contact. Unfortunately, Tuscaloosa sands within 09-04 are locally a poorly oxidized and/or reduced gray. Because coloration is an important criterion of distinguishing Tuscaloosa and Eutaw of medium to coarse sands in absence of diagnostic ichnofossils (i.e., *Ophiomorpha* and *Taenidium*), the first instance of oxidation of sediments and/or overbank lithofacies (*T1*, *T2*) is picked as the Eutaw/Tuscaloosa contact. Moreover, olive-gray to green-black, rounded mud rip-ups that are texturally similar to *E13* and *E14* lithofacies are found within gray, fining upward, medium-grained, moderately-sorted, cross-stratified sand complexes as a basal conglomeratic lag. These basal cross-stratified sand complexes are located at 51.2 to 54.2 meters and 72 to 81.8 meters (Figure 39).

In addition to stratigraphic position of formations, grain-size and lithofacies-stratigraphic trends further elucidate the nature of the overturned fold. Within the upper Tuscaloosa interval, channel sands fine downwards towards clayey *T2* overbank deposits. This is consistent with an overturned Tuscaloosa channel sequence. However, directly above the Eutaw interval at 34 to 46 meters, there are reversals in grain-size and lithofacies patterns as compared to overlying Tuscaloosa channel and overbank complexes. Within the lower Tuscaloosa, a fining-upward pattern is consistent with the overturned-fold hypothesis. Within the Eutaw Formation, grain-size trends of aforementioned basal cross-stratified sand intervals appear to have reversed fining-trends. However, as shown in Figure 52 and discussed within lithofacies descriptions of *E13* and *E14*, there are stratigraphic reversals in the *E13-E14* couplets that likely indicate that they are part of a folded shale lens-variable thickness of *E13-E14* couplets suggest lens geometry. Moreover, there is a repetition of *E10* lithofacies intervals about a middle *E11* lithofacies interval, and the mud conglomeratic lag is observed within multiple locations upper and lower portions of the Eutaw interval. Thus, although vertical lamination and opposing dip directions are found about the vertical dipping, a discrete axial plane for the overturned fold cannot be determined. Instead a hinge zone, *hz*, is delineated as shown in Figure 39. The variable dip angles (Figure 54), complex lithostratigraphic patterns, and fining-trends suggest complex folding which could include second, third order, and/or parasitic folds.

Near the base of the overturned fold, basal *D6* lithofacies show fining-upward trends that suggest that these structureless impactite sands could be fluidized or remobilized channel sands. The overturned fold is interpreted to be intercalated with underlying megabreccia. Although the lower breccia is intercalated with structureless impactite sands, breccia appear similar to overall stratigraphic patterns of the overturned fold reveal a zone of dominant Tuscaloosa clasts and

blocks from 103 to 139 meter depth, a middle Eutaw-dominated breccia from 139 to 167 meter depth and a lower Tuscaloosa-dominated breccia 167 meters to the base of the core at 214 meters; thickness of these zones are 33 m, 28 m, and 47 m, respectively. However, lithic and lignitic clasts of Eutaw, smaller than blocks, do occur locally enveloped by impactite structureless sands outside of the Eutaw-dominated breccia zone. Sedimentological characteristics of megabreccia clasts are similar to lithofacies within the overturned fold. Finally, bioturbated, *Ophiomorpha* sands which are common within the 09-03 drill-core and based on outcrop descriptions of past workers (i.e., Nelson, 2000 and King and Ormö, 2007), bioturbated, *Ophiomorpha* sands are ubiquitous within outcrop as well; however, *Ophiomorpha* sands are completely absent within the overturned fold and lower impactite sands.

Finally, general sedimentological observations and grain-size and inclination logging show significant variability within previously reported stratigraphic intervals (see Figure 53) and decreasing friability with depth. Grain-size and maximum clast size show that maximum clast size generally follows grain-sizes. Further, the upper Tuscaloosa-dominated breccias within the lower impactite sands are generally coarser than lower Tuscaloosa-dominated breccia. Inclinations, as compared to 09-03, are highly variable and less constrained even within the overturned fold. With increasing depth, sandy, conglomeratic, and silty sediments transition gradually from unconsolidated sediments to poorly-lithified sandstone. There should be increasing compaction with depth; however, based on thin-section petrography, sporadic, interstitial, devitrified-glass are contributing silica-cements, particularly within the lowermost 30 meters. At depth, T2 lithofacies do not show significantly greater lithification than T2 intervals in the uppermost reaches.

Figure 52. Grain-size and maximum grain-size for overturned fold in drill core 09-04. a. Grain-size with moving average (black) with a one meter period. Grain-size in phi b. Maximum clast size per 0.2 ft (7cm) with linear scale. c. Maximum clast size per 0.2 ft (7cm) with logarithmic scale. b and c are in millimeters (clast size). Depth is in meters for all graphs. DISCUSSION

Following investigation of the 09-03 and 09-04 drill cores, preliminary interpretations, and literature review of previous work, two fundamental genetic facies of the uppermost impact stratigraphy are identified. The 09-03 drill-core is interpreted to record a long-transport megaslump within its internal extensional/compressional boundary. Late syn-depositional to post-depositional with an underlying megaslump, the resurge facies of 09-03 drill-core is currently the only confirmed record of a Wetumpka resurge. The 09-04 drill-core records the rotational slump of the southeastern, overturned flap. Underlying megabreccia could be an avalanche facies of the rim collapse; however, this author prefers an interpretation of basal shear of a megaslump. The following chapter discusses the deposition of megaslump-formed megabreccias and resurge deposits separately.

Drill Core 09-03, Eutaw-Tuscaloosa megablock-impactite sand complex: interpretations

The *basal shear-mixing zone (R1)* at the base of the resurge marks the underlying megaslump-formed Eutaw-Tuscaloosa megablocks and penetrating, disaggregated impactite sands from the overlying resurge sediments (see Figure 28). Stratigraphic horizons with high concentrations of glauconite have been generally attributed to transgressive ravinement surfaces at the Mooreville Chalk-Tombigbee contact (Savrda and King, 1993; Mancini and Soens, 1994) or condensed sections in general sequence stratigraphy (i.e., Loutit et al., 1998). However, the combination of flame structures, a basal erosive surface, shear-derived deformation immediately below, and superjacent cross-lamination indicate unambiguously rapid burial, hence resurge. These characteristics are inappropriate for a time-intensive surface. Therefore, the base of the R1 lithofacies marks the resurge and underlying, slumped megablock.

The underlying Eutaw-Tuscaloosa megablock is a semi-intact, rotated, mostly complete interval of Eutaw Formation strata intercalated with fluidized and injected impactite sands. Figure (38) shows a series of fining-upward sequences. Within 09-03, a basal, pebbly, partially iron-oxidized, sand is similar to reported basal pebbly, Eutaw sands of Frazier and Taylor (1980). The basal facies is interpreted to be marginal marine and overlying *Ophiomorpha*-bearing sands are interpreted to be shoreface sands (similar to descriptions by Mancini and Soens, 1996). Generally, roundness increases, grain-size decreases, and sorting increases stratigraphically upward. Moreover, a pink mottling is found in upward intervals. Nelson (2000) reported pink sands directly beneath the Mooreville Chalk-Eutaw Formation contact. Although a calcite-cemented, Mooreville-Eutaw contact is not found in 09-03 (as per observations of Savrda and King, 1993; Nelson, 2000), the Eutaw interval in 09-03 is interpreted to be nearly intact due to previously mentioned characteristics and reported thickness. Furthermore, with relatively well-constrained inclinations, the underlying 09-03 megablock is either a rotated or tilted megablock or part of a ramp structure within a duplex structure.

As previously discussed, the Eutaw megablock is intercalated with three zones of disruption which could include stratigraphic intervals of fluidization, brittle and ductile deformation, and clastic injections. Textural equivalents of the enigmatic matrix sand of *dz1* have not been observed in the field, existing literature, and is better-sorted than most clastic dikes. However, the enigmatic sand of *dz1* is found within one short interval beneath *dz2*, contains rotated breccia of lithofacies *D2* exists below the basal gravelly facies of *E6*, and appears to be above the probable Tuscaloosa interval of lithofacies *T1*. Furthermore, breccia clasts are derived from the overlying Eutaw interval and are more common in the upper portion of the *dz1*. Hurst et al. (2011) state that clastic sills characteristically have erosional sediments

derived from the upward wall rather than the lower one. Therefore, because *dz1* is likely present at the Eutaw and Tuscaloosa contact and contains brecciation characteristic of clastic sills, *dz1* is interpreted to be a probable clastic sill of unknown sedimentary source.

Disrupted zone 1 (*dz1*) clearly has at least two stages of deformation. An initial stage includes brittle (meso-scale reverse and normal faulting), ductile deformation (convolute lamination), and fluidization followed by clastic dikes that have cross-cutting relationships with pre-existing deformational fabrics. Typically, clastic dikes show weak laminae sub-parallel to dike walls in conventional settings (Petersen, 1968; Hurst et al., 2011). In impact settings, clastic dikes have some wall-parallel lamination along with a substantial amount of entrained breccia (i.e., Sturkell and Ormö, 1997). As shown in Figure 25, clastic dikes of *dz2*, dikes show some sub-parallel laminae; however, as shown in Figure 25, some turbulent features exist within these dikes. Furthermore, unlike observations of Sturkell and Ormö (1997), drill cores of *dz2* show dilation of existing sediments but do not show substantial brecciation of dike walls nor injection of allogenic breccia as compared to examples of Lockne impact structure. Fining-upward sands of the clastic dike network are interpreted as evidence for upward injected sediments. Thus, the secondary sand injections are attributed to impact-derived over-pressuring of underlying sediments rather than impact-derived compression-rarefaction dilations (described by Sturkell and Ormö, 1997; Horton et al., 2008) that inject sediments downward from upward strata or surficial deposits.

On the other hand, *dz2* primary structureless and fluidized fabrics contain coarser, more angular and more feldspathic sediments than surrounding Eutaw sands. Moreover, fluidized and structureless sands (*D1*, *D2* lithofacies) within *dz2* have sporadic occurrences of devitrified glass along with exotic components of heavy minerals and a large shattered feldspar crystal. This is

evidence for underlying source of injected material probably along a zone of shear (i.e., fault) as evidenced by gradational and associated conjugate faults and tight, convolute and recumbent folding.

Further evidence for macro-scale faulting at *dz2* include the secondary dikes and a tight, underlying fold (e.g., drag fold) with accompanied, internal, and locally-derived clastic dike-similar to fold-dike associations by Strachan (2008). Unless evidence shows prior existence for clastic dikes, i.e., cross-cutting relationships, clastic injections follow areas of extension and lower pressure, normal faulting, or follow pre-existing faults due to mechanical anisotropy (Hurst et al., 2003). Thus, *dz2* is likely the site of a significant fault with a possible, secondary reactivation.

Disrupted zone 3 (*dz3*) does not have associated faulting and clastic injections such as *dz1* and *dz2*. Instead, *dz3* has moderately-sorted, homogeneous impactite structureless sands with sporadic breccia of locally derived *E1* intervals and an admixture of rare, exotic components such as biotite. Genetic origin of this zone is enigmatic. Superjacent resurge sediments have an erosive relationship with *dz2* but do not appear to inject into *dz3* nor do *dz3* sediments inject into overlying resurge intervals. Speculatively, this interval could be a thin veneer of back-slumped Eutaw sediments from adjacent folded-tilted megablocks to the north (i.e., the “cliffs”). Another possibility is that these sands are sub-aerial, extrusive bodies of injected sands, deposited shortly before the arrival of the resurge proper. Less likely, this interval could be a cataclasis zone for a shear zone immediately beneath the resurge interval; however, substantial drill-core loss and massive character of the sands do not allow for interpretation for their genetic origin.

Drill Core 09-03: emplacement of mega-slumps and entrapment of resurge stratigraphy

The overlying marly resurge sediment contains inclinations in excess of angle of repose. For example, a study by Kenter (1990) demonstrates that granular carbonate sediments can have a maximum slope of 35°, but carbonate mud settings in the modern Bahamas have inclinations less than 4 degrees. Thus, taking its fine-grained, marl compositions into account, the inclinations of the resurge interval are clearly beyond the angle of repose. Furthermore, there is no intercalation of avalanched, slumped, or significant admixture of crystalline basement, Tuscaloosa Group, Eutaw Formation sediments and clasts. Because the resurge interval should be emplaced after most slumping and avalanching of the southern rim (i.e., King et al., 2006), the resurge interval of the “chalk meadow” is interpreted to be a half-graben-like structure that has structurally-preserved a mostly complete interval of resurge facies. Thus, the listric fault that likely tilted or rotated the resurge interval intersects the Tuscaloosa-Eutaw megablock as depicted in Figure 55. From observations of 09-03 drill-core, the *dz2* interval is interpreted to be the faulted location of greatest likelihood. Conversely, Poag et al. (2004) describe post-impact compact-driven, basement-derived extensional faulting in seismic studies which could account for the down-thrown block (J. Ormö, personal communication, 2011). However, post-impact graben and half-graben structures of the Chesapeake Bay impact structure have radial geometries on plan view and relatively high angles in seismic section (cf. Figure 7.11 and 7.12 in Poag et al., 2004). Thusly, basement-driven faulting seems unlikely as “chalk meadow” exposures do not have radial geometries as seen in Figure 1 of this report. Instead, “chalk meadows” are seemingly about a roughly linear west-east axis.

Figure 55. Proposed cross-section of an area near core hole 09-03. Inferred structure based on the field observations, existing literature (Nelson, 2000), inclinations, and disrupted zones within 09-03 drill-core. Dashed lines are possible normal faults. Solid line is probable normal fault that intersects d_2 .

General structural models for slumping could explain the preservation of the resurge facies as a downthrown and/or tilted block with associated, compressional folding in the “cliffs” to the north. As discussed by Bradley and Hanson (1998), an idealized slump is composed of an extensional regime and compressional regime delineated about a line of lateral detachment which is manifest as a slip face. The forward-moving “toe” is characterized by a general transition, in order, from symmetrical folds, asymmetrical folds, to sheath folds with a corresponding transition from pure-shear (symmetrical folds) to simple shear (sheath folds). Bradley and Hanson (1998) used stereographic methods to determine vergence; direction of vergence is inferred to be paleo-slump direction. However, without a fully oriented drill-core and a well that intersects the axial plane, this kind of analysis is likely not possible. Nonetheless, as seen in Figure 55, a general sense of vergence can be appreciated by simply observing fold geometries within asymmetrical folds. A similar, asymmetrical geometry has been observed within the “cliffs” (cf. Figure 40 in Nelson, 2000). This

fold within the western megablock is interpreted by the current author to indicate a northerly sense of vergence and hence, a northerly sense of paleoslump direction (Figure 56).

Figure 56. Idealized slump model. Note forward compressional regime that transitions from symmetrical folds to sheath folds in the “toe.” Extensional zone is behind compressional zone. From Bradley and Hanson (1998).

Figure 57. Models demonstrating slump vergence. (Left) models demonstrating slump geometry for vergence (paleoslump direction) in an asymmetrical fold. (Right) General transition from symmetrical (pure shear) to sheath folds (simple shear). Stereographic plots are to the right. Stereographic methods were not utilized within this study. From Bradley and Cooper (1998).

Figure 58. Asymmetrical fold of the “cliffs”. Blue line is an interpreted, correlated overbank bed. Black line is the axial plane of fold. Red line is approximate hinge of asymmetrical fold. North is to the right. Vergence is to the right, hence northerly,plaeoslump direction.

Similar to the idealized slump model of Bradley and Hanson (1998), analog modeling of over-pressured slumps by Vendeville and Gaullier (2003) produced a “toe” of compression, and across a passive boundary, deformation was characterized by extensional shear (e.g., normal faulting). Their experiment involved underlying sand over-pressured by either compressed air or water, an intermediate layer of sealing clay or silicone and an overlying cover of water and sand. With tests that involved either compressed air or rapid slumping in water, a buckle folded and thrust-faulted “toe” resulted, and a normal faulted extensional region resulted beyond a passive boundary. Where normal faults breached the impermeable mid-layer, they became foci for “fluid escape” (clastic dikes). Interestingly, the layer that experienced the most shear was the lower basal sand, not the cover or impermeable layer.

The Vendeville and Gaullier (2003) model is thought by this author to be analogous for both entrapment of the resurge and sub-surface mobilization. If the “chalk meadows” are in fact within an extensional region of a mega-slump, the resulting graben or half-graben may have provided a structural trap that preserved them to present day. Moreover, if the resurge was partially syn-depositional with slumping, the fine-grained marl of the resurge would act as an excellent seal for overpressured fluids within the megablocks. With active evolution of the mega-slump or early settlement of the crater-fill breccias, normal faulting and the downthrown resurge stratigraphy would breach the resurge seal and injected sediments and fluids along normal faults and upon surface.

However, at this time, the modern, surficial contact between the “chalk meadow” and neighboring Eutaw megablock is poorly exposed and partially obscured by a road. Thus, trenching may be necessary to find evidence of expelled fluids and sands. Furthermore, intercalated slumped blocks have not been observed within the field nor in the drill core and

neither have currents and sediments of the resurge interval appear to have been affected by a significant topographic low. Therefore, if an extensional regime within a mega-slump is responsible for preservation of the resurge, then the resurge front must be immediately behind the active front of the mega-slump. Alternatively, post-slumping compaction-derived subsidence could preferentially appear along pre-existing, slump-derived faults. However, the presence of secondary clastic dikes suggest a sudden outlet of escape before significant over-pressuring dissipated; therefore, if subsidence is the cause of resurge preservation, then subsidence must have occurred shortly after deposition of the resurge.

Drill Core 09-04: Slumped overturned flap and underlying impactite sands

The overturned fold sequence is interpreted as proposed by King et al. (2010) to be a slumped portion of the southeastern overturned flap. As evidenced by fining-downward trends (Figure 39), the upper Tuscaloosa interval is overturned whereas underlying Tuscaloosa is fining-upward. Thus, with the interceding Eutaw stratigraphy between two Tuscaloosa stratigraphic intervals and proximity to likely crystalline ejecta along the southeastern rim, this is strong evidence that this is part of the preserved overturned flap. However, as evidenced by variable, inclination trends and multiple repetitions of lithofacies within the Eutaw stratigraphy, the resulting geometry of the slumped overturned flap is highly complex. Based on inclinations, the overturned flap currently has secondary to tertiary folds. Also, undulating, deformed contacts observed on overbank/cross-stratified contacts could be indications of self-similar behavior (i.e., parasitic folds) of larger scale folding.

Furthermore, the 09-04 well likely penetrated the nose of the overturned fold, but the drilling was off-center. As can be seen the “hinge zone” is off-center which could be explained if the well penetrated the “nose” of the overturned flap and possibly if the overturned flap is

rotated. Also, although Eutaw Formation is definitely present, the sedimentological characteristics are interpreted for a lower Eutaw unit of incised valley fill.

As discussed in target stratigraphy, biotite is a common constituent within regional exposures of Emuckfaw Group. Also, biotite along with plagioclase is a comparatively common constituent of the 09-04 Eutaw intervals as compared to 09-03 mineralogical composition where muscovite is the predominant mica. However, biotite is considerably less chemically stable than muscovite with laboratory results showing muscovite with two orders of magnitude greater resistance to weathering than biotite (Leonard and Weed, 1970). In the Eutaw in this area, the biotite grains had short transit time, are locally derived, had low subaerial exposure, and are unlikely to have been significantly reworked (i.e., within shoreface and beach settings).

The fossiliferous clayshale (*E10*) lithofacies is possibly analogous to the “Ingersoll shale” (described by Bingham et al, 2008), a tidal-channel fill of a lower Eutaw incised-valley fill that is part of the lowermost transgressive systems tract. The *E10* lithofacies is clearly lens-shaped due to highly variable thicknesses of a double occurrence of a structurally repeated bed (see Figure 39); likewise, the Ingersoll shale is similarly lens shaped. Also, the *E10* lithofacies is fossiliferous with macerated plant material along laminae. However, the *E10* lithofacies is finer-grained, less fossiliferous (but no vertebrate fossils), and does not appear to have substantial amber content as compared to the Ingersoll shale. Nonetheless, this is interpreted to be equivalent in environment of deposition due to sedimentological characteristics, and tidal setting. Also, the *E10* lithofacies along with the silty lignite of *E14* are likely the source for various green, uncommonly carbonaceous, rounded mud clasts that reoccur as either a lag deposit within Eutaw intervals, a conglomeratic lens, or an admixture within Eutaw-derived, disaggregated impactite sands.

Sedimentological and stratigraphic characteristics taken as a whole, indicate that the Eutaw intervals of 09-03 are a basal package of incised valley fill within original (undeformed; pre-impact) stratigraphy. Within literature for extra-crater outcrops of Eutaw Formation (Mancini and Soens, 1994; Savrda et al., 1996; Savrda and Nanson, 2003), locally for the Wetumpka impact structure (Nelson, 2000; King and Ormö, 2007) and the 09-03 core demonstrate that *Ophiomorpha*-dominated sands are ubiquitous within the Eutaw Formation. Yet, not a single occurrence of *Ophiomorpha* sand is observed in either the overturned flap or the underlying megabreccia. This could mean that the geometry of the fold and relationship to drilling is such that the upper Eutaw stratigraphy is adjacent to the 09-03 core hole (at the cliffs).

Alternatively, the upper Eutaw could have been part of the original, target stratigraphy at 09-04 but is no longer present. In Ormö et al. (2002), excavation flow during the formation of Lockne crater is thought to have removed part of the sedimentary cover along a low-angle discontinuity surface. This surface would have formed before the overturned flap was completely formed. Likewise, a similar phenomenon could have occurred at the Wetumpka impact crater which removed the Mooreville Chalk and a significant, upper interval of the Eutaw Formation.

As reported in results, semi-intact megablocks within the lower impactite sands mirror the stratigraphic pattern of the semi-intact overturned flap. Also, impactite sands appear to be mostly disaggregated intervals of Eutaw, within the Eutaw-dominated section and could be Tuscaloosa-derived in Tuscaloosa dominated sections. There are a number of possibilities for the relict stratigraphic order.

Although the stratigraphic similarities of the overturned flap and apparent relict stratigraphy of the lower impactite sands could be happenstance, it is thought by this author to

give us some insight into the mode of emplacement within the crater. First, during the collapse of the southeastern rim, the overturned flap may have “avalanched” into the southeastern quadrant with a systematic shedding of material that reflected the stratigraphic order of the overturned flap. In this scenario, the Eutaw Formation must be partially excavated as previously discussed. Collapse of the rim (once the transient crater ceases to expand) results in crater-filling breccia from slumping, landslides, and the formation of rim terraces (Melosh and Ivanov, 1999). In crater-filling breccias of the Chesapeake Bay impact structure, Gohn et al. (2009) interpreted crater-filling “diamicton” as consequence of avalanching of the collapsing rim in which sliding masses of the rim break up by dilational processes into discrete blocks with a resulting evolution to debris flow. A similar process could have occurred with the southeastern rim. In this scenario, the overturned flap could not be part of the hinge. Instead, the overturned flap would be a secondary fragment that would slump onto a forward avalanche. This is possibly supported by swirled fabrics that indicate some form of shear between the overturned flap and lower impactite sands.

A second possibility is that the 09-04 shows a severely rotated, rotational slump. In this scenario, the large amount of accommodation space is interpreted in gravity modeling (Figure 3) and evident in the considerable depth of the true crater floor at the edge of the crater (> 251 m depth). This may create more rotation in the slumping rim which due to soft-sediment deformation and overturned stratigraphy would create a highly, complex fold and stratigraphic architecture (cf. examples of slumping in Ricci, 1995). Furthermore, in non-impact settings, Bradley and Hanson (1998) observed basal shear zones with disaggregated sediment and internal clasts that resemble the common contorted mega-clasts of the impactite sand interval of 09-04 (see Figure 59). Also, Strachan (2008), again in non-impact settings, observed and described

“flow transformations” in which cohesive sub-aqueous slumps progress with increasing folding until brittle deformation and clastic injections result near hinges of folds. Consequently, with increasing deformation, slumps brecciate into debris flows. Following the work of Strachan (2008), folding and consequential overpressure are the true cause of a transition from slump to debris flow. Thus, it is possible despite the relative short distance of transport for slump to debris flow rather than avalanche to debris flow if sufficient folding and over-pressuring are present.

Figure 59. A possible analog for the slumped, overturned flap of drill core 09-04. Note the shear and contorted and dismemberment of bedding along a basal shear. This was originally a study of sub-aqueous deep basin Devonian slumps within Maine. From Bradley and Hanson (1998).

Although the stratigraphy of 09-04 could have resulted from avalanching, slumping, or a combination of mass-wasting mechanisms, the stratigraphy is not the result of fallback ejecta. Fallback ejecta should incorporate a considerable amount of crystalline ejecta. Instead, semi-

intact boulders and blocks of the impactite sand are of sedimentary strata but very little crystalline clasts are encountered except at the base of the well. Furthermore, heavy mineral percentages fall under 1%, which is consistent with normal Tuscaloosa Group heavy mineral content (see Target Stratigraphy). However, the presence of euhedral, shattered garnets, epidote, and sporadic interstitial glasses suggests that some ejecta admixture is present. Possibly, suevite or ejecta breccia constituents were upwardly injected into the sediments of the collapsed rim.

Finally, although post-impact hydrothermal effects are not an objective of this study, observations for hydrothermal conditions and substantial alteration of minerals are observed. overbank deposits of Tuscaloosa Group (*T2*, *T3*) should not be calcareous based on existing literature of the Tuscaloosa. However, upward boundaries of *T2-T3* blocks have evidence of reduction with associated calcium carbonate precipitation that diminishes with depth. Therefore, this could indicate a downward directed calcium bicarbonate enriched groundwater (derived from seawater?) that has precipitated calcite within the less permeable intervals, suggesting evidence for a post-impact convectional hydrothermal system. Also, common chloritization of micas and plagioclase are present. Chloritization of biotite is commonly associated with hydrothermal systems (i.e., Parneix et al., 1985; Ezzaim et al., 1999). However, chloritization of biotite has been demonstrated to occur in low temperature, near surface settings. Within the Tuscaloosa of sub-surface Louisiana of the central Gulf of Mexico, reservoir sands have chlorite linings along with chloritized biotite micas. Ryan and Reynolds (1999) demonstrated that near surface weathering and alteration of ultramafic clasts within the Tuscaloosa sediment facilitated the chloritization of biotite and precipitation of chlorite clays. As reported by Neathery et al. (1976), an amphibolite bed exists in the eastern rim which could have similarly facilitated the chloritization of biotite as geochemical processes described by Ryan and Reynolds (1999).

Drill Core 09-03: Resurge Deposition

Granulometric, statistical approaches, such as those conducted by Ormö et al. (2007) or Ormö et al. (2009), were not attempted because marl clasts could not be distinguished with the unaided eye nor could clasts be delineated consistently enough by X-ray CT. Nevertheless, in concert with paleocurrent directions (Figure 27), sedimentary structures and lithofacies characterizations could be used in conjunction with established resurge characteristics to interpret some aspects of the Wetumpka resurge.

First, paleocurrents do not have true azimuth directions. However, based on previous discussions about structural features of the “chalk meadow,” a listric fault is assumed to exist along the surficial trace of the Eutaw-Mooreville Chalk contact. Assuming any resulting deformation (i.e., drag folding), tilting, or rotation would have produced strikes sub-parallel to this trace, an inferred north can be determined (Figure 27). However, with paleocurrent data, tectonic adjustments are unnecessary for tilting under 25° ; beneath 25° , azimuth parameters are altered less than three degrees (Potter and Pettijohn, 1977). Dipping of sub-horizontal features within the resurge exceed 25 degrees. However, without a true understanding of the structural configuration of the “chalk meadow,” any tectonic adjustment is somewhat speculative. On the other hand, almost all paleocurrent and fracture inclinations, with the exception of basal inclinations, exceed the associated sub-horizontal dip. Thus, the tectonic adjustment would not reverse the dipping direction. Therefore, the data is still reliable to determine broadly defined direction, (i.e., approximately north or south).

Although resurge is mostly determined by debris-flow characteristics, the base of the resurge has both flame structures and overlying cross-laminations with increasing inclination upward. Moreover, unlike overlying intervals, the mineralogical composition is exceptionally

glaucous. In fact, other than intact Mooreville Chalk-Tombigbee Sand clasts (e.g., *R4* lithofacies), glauconite is dispersed within resurge matrix; the high glauconitic content has been interpreted by King et al. (2010) to indicate the resurge sediments are sourced distally from deeper Mooreville Chalk. Therefore, based on the presence of the cross-lamination set, the front of the intruding resurge was aqueous in character, and based on paleocurrent directions, the initial resurge deposition was northward directed from a deeper, distal source.

On the other hand, as seen in Figure 27 the resurge-megablock contact inclination supersedes the superjacent inclinations. Therefore, this could indicate a southerly directed current. However, by rotating the basal contact to 0° and subtracting the rotated angle from the superjacent series of angles, the overlying series of inclinations reverse from increasingly inclined to decreasingly-inclined upward; a stratigraphically higher interval of trough cross-stratification is increasingly-inclined upward. Also, inclinations of originally sub-horizontal features are variable and the basal contact supersedes overlying originally sub-horizontal indicators. Because the basal inclination exceeds subsequent, originally sub-horizontal inclinations and combined with previous points; the rotation of the resurge-megablock contact is interpreted to be syn-deformational with early resurge deposition. Consequently, the amount of rotation of underlying units at onset of resurge deposition was likely 14° rather than 43°; thus northward directed currents.

For possible mode of deposition of these impact deposits, there are a some rare, reversed laminae (herringbone cross-stratification) within the basal *R1* interval and a flame structure at the base; these are known non-exclusive sedimentary structures of tsunamiites (Matsumoto et al., 2008; Fujiwara, 2008). Lithofacies *R1* relative thinness (0.2 m) is also supporting evidence of tsunami origin. However, the overlying units within the resurge are substantially thick and are

evidence against *R1* lithofacies as part of the oscillatory resurge (i.e., tsunami wave train). Therefore, the *R1* lithofacies is part of the resurge proper, the initial deposition of the true resurge. However, how this unit relates hydrodynamically to the rest of the resurge remains a mystery.

The overlying unit above the basal *R1* lithofacies is a matrix-dominated breccia interval (*R2*). Based on the sedimentological characteristics reported in results, the overlying *R2* interval is a matrix-dominated debris flow as defined by Tripsanas et al. (2003) as having less than 5% clasts. Poorly-defined stratification is interpreted by Tripsanas et al. (2003) to indicate “successive surges” and hydroplaning of the overall flow. However, stratified matrix-dominated flows are also reported to have inverse grading. Matrix of the lower resurge appears to have weak normal grading.

In non-impact settings, studies of “debrites” within deep ocean basin plains resemble sedimentological characteristics of the lower resurge. Overall, the basal *R1* and *R2* lithofacies resemble stratigraphic descriptions of a “debrite” sequence by which they have a basal laminated and massive, relatively better-sorted sand overlain by a matrix-dominated breccia. Within the “debrite,” breccia clasts are boulders that have long axis aligned parallel to bed base. Similarly, although the *lower resurge* is much thicker, *R5* lithofacies of chalk and marl boulders are tabular in shape and have apparent alignment with matrix laminations. However, unlike descriptions by Talling et al. (2010), tops of *R5* lithofacies have frozen, dilational brecciation (Figure 60). Although, the specific cause is unknown, this brecciation could be caused by a passing solidification front within the debris flow during deposition (for discussion of solidification front within fluidized flow, see Sassa et al., 2003). As the solidification front passes through an *R5*

clast, there could be a differential shear that may have created the upward suction. However, further study may be required to fully explain this brecciation.

Figure 60. A stratigraphic analog for the *lower resurge* from deep basin plain setting. According to Talling et al. (2010), this “debrite” traveled 45 km above a hydroplaning base. Modified from a figure in Talling et al. (2010).

The contact of the lower resurge and mid-resurge is somewhat irregular, but a probable inclination was derived for an originally sub-horizontal contact. Downward injection of resurge matrix, subtle load casts, and contrasting attenuation values within X-ray CT suggest different densities between mid-resurge and lower resurge. Possibly, fracturing and downward injection reflects an upward suction.

Drill Core 09-03: mid-resurge, evidence for anti-resurge

The mid-resurge as a whole is interpreted to be the anti-resurge equivalent of Wetumpka resurge. As discussed by King et al. (2006), resurge would have been disproportionately strong from the south due to the southern collapsed rim and the resistant barrier of the northern

crystalline rim. Therefore, returning water would not likely converge on a central location and create a well-defined central plume. However, the resurge may have progressed towards the northern rim where resurge proper crashed against that barrier and created an “outer-wall” which would then behave similarly to a central plume along the interior of the northern crystalline rim. Consequently, after piling up against the northern rim, the resurge would reverse back to sea, and thus create an anti-resurge. This concept is supported by the mid-resurge of the 09-03 drill-core.

The 09-03 mid-resurge is a clast-supported marl and chalk breccia as revealed by X-ray CT. According to Ormö et al. (2007), anti-resurge deposits are characterized sedimentologically by the following: gradual reverse grading in clast size; better washing but less sorting in clasts; and reworking of resurge proper sediments. Based on imbrications of marl and chalk clasts, initial currents are variable but progress into well-defined south directed currents. Qualitative assessment of clast size reveals both reverse grading and normal grading; however, if two “pulses” are present, then each pulse is likely normally graded. This is in contradiction with observations by Ormö et al. (2007) for reversely graded anti-resurge units. On the other hand, matrix grain-size trends show reverse grading. Mid-resurge matrix is relatively sandier than underlying matrix within the lower resurge, and reworked clasts are comparatively well-rounded, indicating traction transport. Waning flow led to a transition from a conglomeratic deposit to trough cross-bedded glauconitic sand which is also southward directed. Subsequently, thin variably directed, clast-supported breccias suggest variable current directions. However, using the wall-plume concept, anti-resurge flow should be quite variable and likely interweaving.

09-03: upper resurge: slumping and rapid suspension fallout

Clast-dominated breccias grade upward into contorted, sub-vertically laminated, mud-dominated breccias. This deformed interval is interpreted as slumping due to either adjustments

following anti-resurge deposition or further subsidence of the proposed half-graben structure. Exceptionally fine-grained and normally graded calcareous silts above the slumped interval are likely rapid suspension fall out of suspended fine sediment within the oscillatory phase of the resurge.

09-03: uppermost resurge: slumping or tsunamiite?

The exceptionally fine-grained upper interval of the upper resurge is truncated by a clast-dominated breccia and transported boulders of Mooreville Chalk. Due to reduction in data quality in the uppermost three meters and an incomplete record, interpreting this interval is problematic. Although chalky clasts and a one rare schist clast are located at the base, sedimentary structures are absent. Due to the size of the overlying block at the top of the drill-core, the uppermost resurge is interpreted to be a post-impact, resurge-deposit slump as sedimentary structures for tsunamiites are absent (i.e., basal flame structures, herring-bone cross-stratification, winnowed tops, etc.).

Enigmatic Composition of Wetumpka's Resurge

The most important characteristic of the Wetumpka resurge is the exceptionally homogeneous lithology of transported clasts. Despite having a diverse target stratigraphy, the resurge of Wetumpka is almost exclusively sourced from Mooreville Chalk, the uppermost and thinnest stratigraphic target unit. Other well-studied impact craters such as Chesapeake Bay and Lockne craters have diverse, mixed target but have a full, lithologic range of constituent clasts even if a particular lithology is predominant. Where preserved, extra-crater resurge deposition has similar diversity (see the Alamo impact structure discussed by Pinto and Warne, 2008). However, although interpretations can be made on the local mode of emplacement with the 09-03 and 09-04 drill-cores, with a lack of evidence rather than actual evidence, any explanation is

widely speculative. Therefore, this will likely remain an open question for further research at Wetumpka.

Chronostratigraphic timing of the Wetumpka Impact Event

Wartho et al. (2011) established a radiometric date of 84.4 +/- 1.4 Ma for the Wetumpka impact structure. However, within the resurge sediment and in outcrops of semi-intact Mooreville Chalk (see Nelson, 2000), chalky clasts and an interbedded chalk bed are observed, respectively. Consequently, using the stratigraphic framework of Liu (2007) in Figure 4, the Wetumpka impact event is further chronostratigraphically and lithostatigraphically constrained to a range of between 83 and 84 million years. This range is delineated based on the first chalky interbedding and the upper limit of error on the 84.4 +/- 1.4 m.y. radiometric date. This chalky interbed is located in the lower CC17 biostratigraphic zone. Currently, only one chalky interbed is observed within semi-intact Mooreville megablocks of Nelson (2000). Moreover, resurge sediments are predominately marl versus chalk. Also, because a lower target water thickness is suggested by Ormö (2010), the present author suggests that the Wetumpka impact occurred in a regressive phase within the deposition of lower Mooreville Chalk. Thus, as marked by Figure 4, the Wetumpka event occurred in the lower CC17 during a brief regression of an approximate age of 83.9 million years ago.

CONCLUSIONS

Based upon observations of the 09-03 and 09-04 drill-cores, the following bulleted conclusions have been determined towards the objectives stated in the Introduction.

- **Lithofacies and general stratigraphy of drill cores 09-03 and 09-04:** The lower part of 09-03 contains a tilted-rotated Eutaw-Tuscaloosa megablock with three intercalated, deformational, and disrupted zones. The original stratigraphy of the

megablock is characterized by the lithofacies in stratigraphic order of appearance: *micaceous, massive Tuscaloosa sand (T1); trough cross-bedded sand (E6); bioturbated, cross-laminated sand (E7); bioturbated, massive sand (E1); bioturbated, interbedded sand and mud (E2); sheared, bioturbated sand (E8); and sheared, cross-laminated sands; fluidized sand* that are intercalated by *structureless, impactite sands (D1); fluidized impactite sands (D3); and clastic dikes (D2)*. The Eutaw-Tuscaloosa megablock is overlain by resurge lithofacies, specifically: *basal shear-mixing zone (R1); matrix-dominated breccias (R2); clast-dominated breccias (R3); transported Mooreville Chalk(R4); poly lithic-laminated matrix (R5); and enigmatic chalk (R6)*, which are constituents of stratigraphic informal units of *lower-resurge, mid-resurge, upper-resurge, and uppermost resurge*. The lower part of 09-04 is an impactite sand with entrained blocks of Tuscaloosa and Eutaw, namely these lithofacies: *overbank/paleosol mud (T2); overbank/paleosol sand/sandstone (T3); contorted, laminated sand/sandstone (T4); fluidized sand/sandstone (T5); cross-stratified sand/sandstone (T6); sandy lignite (E15); contorted, laminated sand/sandstone(E7); grayish-green to green-black; mud conglomerate (E8) in an impactite sand matrix of Massive, structureless, impactite sand/sandstone (D1); fluidized impactite sand and sandstone (D2); contorted, impactite sand/sandstone (D5); massive, structureless, granular-pebbly impactite sand/sandstone (D6); and inclined, poorly-moderately stratified impactite sands/sandstone (D7)*. The impactite sands and entrained semi-intact blocks are overlain by a slumped, overturned flap of semi-intact, heavily folded, Tuscaloosa and Eutaw lithofacies, namely: *overbank/paleosol mud (T2); overbank/paleosol sand/sandstone (T3; contorted, laminated sand/sandstone (T4);*

fluidized sand/sandstone (T5); cross-stratified sand/sandstone (T6); sandy lignite (E15); and contorted, laminated sand/sandstone (E7)

- **Mode of emplacement of the Wetumpka resurge:** The resurge interval of drill core 09-03 is divided into four stratigraphic divisions: *lower resurge*, *mid-resurge*, *upper resurge* and *uppermost resurge*. Stratigraphic and sedimentological observations along with azimuth directions inferred from oriented drill core with an inferred extensional structure allow interpretations of mode of emplacement and general direction of resurge flow. The following characterizations and interpretations are given by Ormö et al. (2007) and King et al. (2006). **(1)** The *lower resurge* is a matrix-dominated debris flow with a general northerly flow that has poor stratification, entrained Mooreville Chalk clasts up to 1 meter in stratigraphic thickness, and a basal, mixing zone with cross-laminated, heavily glauconitic sand. This is interpreted to be the “resurge proper” and hydrodynamic mode of emplacement could be similar to stratigraphically analogous, hydro-planing, debris flows (see Talling et al., 2010). **(2)** The *mid-resurge* is a clast-supported breccia or conglomerate that is generally southerly directed, has moderately imbricated and normal grading clasts, reverse grading of sandy-marl matrix, and is capped by trough cross- stratification or possible oscillatory ripples. This interval is interpreted to be an “anti-resurge” equivalent derived from seaward flow from a “wall-plume” rather than a central plume (see King et al., 2006). **(3)** The *upper resurge* follows clast-supported breccias and generally fines upward into silty and clayey marl above a contoured and chaotic lamination of interpreted slumping of resurge deposits. This is interpreted to be part of the “oscillatory resurge” and involved rapid deposition of

suspended particles. (4) The *uppermost resurge* represents either post-impact slumping of resurge sediments or a late arriving tsunamiite. However, because of an incomplete record, heavy weathering, and some limited loss of core, interpretation of the *uppermost resurge* is problematic.

- **Structural entrapment and preservation of resurge deposits:** The uppermost impact stratigraphy of the resurge facies is preserved at Wetumpka because of structural traps. The Eutaw-Tuscaloosa megablock beneath the resurge strata has moderately constrained inclinations with a mean dip and rotation-tilting of ~30 degrees. Comparisons with the well-studied “cliffs” locality, location of the “chalk meadow,” and resurge inclinations that exceed the angle of repose suggest that the “chalk meadow” is part of a local extensional zone within a megaslump. Therefore, the “chalk meadows” of resurge deposition are at least partially preserved by local graben or half-graben structures. Alternatively, resurge deposits are preserved due to post-impact subsidence-derived graben or half-graben structures analogous to similar structures at Chesapeake Bay (see Poag et al., 2004).
- **Disrupted zones of the Eutaw-Tuscaloosa megablock (09-03):** From observations within the 09-03 drill core, three zones of disrupted strata are observed within the megablock. The lowermost zone (*dz1*) is interpreted to be a clastic sill between the Eutaw Formation and Tuscaloosa Group from an enigmatic source. The middle zone (*dz2*) is a brittle to ductile to fluidized zone that is interpreted to be a fault zone within the mega-slump complex. The *dz2* also shows evidence for a secondary deformational event. Clastic dikes that have cross-cutting relationships with pre-existing deformational fabrics are interpreted to indicate that a resurge seal was

breached by extensional faulting. The *dz3* zone is likely pre-resurge deposition back-slumped sands from neighboring megablocks.

- **Original Eutaw Stratigraphy of the Wetumpka Area:** Sedimentological and stratigraphic observations of the semi-intact Eutaw intervals within drill cores 09-03 and 09-04 allow increased understanding of original, general Eutaw stratigraphy for the Wetumpka area. The target Eutaw Formation consists almost entirely of the lower unnamed member of the Eutaw Formation. From 09-03, the Eutaw Formation is divided into two stratigraphic parts. A “lower” unit within the Eutaw Formation is poorly lithified, moderately bioturbated cross-stratified, marginally subfeldspathic to quartzose sands with sparse gray, bioturbated, and interbedded clays. The lower unit contains a basal pebbly, coarse sand that is weakly to moderately cemented by iron-oxides. In contrast, the “upper” unit of Eutaw Formation is a heavily bioturbated, medium to fine-grained, rounded, and moderately to well-sorted quartzose sand. The upper unit is exceptionally friable and has both interbedded bioturbated white clays and cross-stratified sand lenses. A pink mottling is diagnostic for the upper Eutaw. Locally, incised valley-fill facies of tidal flats and channels exists in the basal Eutaw Formation. The true, stratigraphic thickness of the Eutaw Formation is a minimum of 34 m within 09-03.
- **Mega-slump of Overturned Flap:** King et al. (2010) proposed that the 09-04 well penetrated the overturned flap based upon reversed stratigraphy of Tuscaloosa, Eutaw, and then Tuscaloosa and sub-vertical bedding near a “hinge” within the penetrated Eutaw Sand. King et al. (2010) also described the lower interval of 09-04 as “impactite sands.” Following detailed analysis of the 09-04 drill-core, grain-size

trends show fining-downward trends in the upper Tuscaloosa interval and fining-upward in the lower trend. Grain-size trends confirm that the uppermost 100 m belong to a slumped overturned flap. However, variable inclinations and repetitions of beds before the sub-vertical bedding suggest complex secondary and tertiary folding following slumping of the overturned flap. In the lower impactite sands, original stratigraphy of megaclasts resembles the overlying stratigraphic pattern within the overturned flap. Thus, the lower impactite sands are interpreted to be disaggregated intervals of the overturned flap as well. Petrography of impactite sands show accessory minerals <1% which are well within range for Tuscaloosa Group. However, shattered euhedral garnets, intact epidote-zoisite crystals, and sporadic glass demonstrate some disaggregated crystalline basement has been entrained or injected upward into the slumped or sheared lower part of the overturned flap (lower impactite sands).

- **Stratigraphic timing of the Wetumpka impact event:** The radiometric date of 84.4 \pm 1.4 m.y. (Wartho et al. (2011) is further stratigraphically constrained by sparse chalky clasts within resurge sediments and a chalky interbed within semi-intact Mooreville Chalk megablocks described by Nelson (2000). Using the upper boundary of the radiometric date and the first chalky bed within the stratigraphic framework of Liu (2000), the age of the Wetumpka impact is constrained to a range of 83 to 84.4. Assuming that Wetumpka occurred within a regressive phase and only one chalky bed is present within Wetumpka target stratigraphy, an approximate age of 83.9 million years ago is suggested.

APPENDIX

Point Count Data from thin-section petrography of drill core 09-04 samples.

N is total point counts. Mx is matrix, Q is Quartz, F is feldspar,

L is lithic fragments, and Por is porosity.
