#### Abstract

The purpose of this study was to determine if post surgical processing affected the dimensions of skin samples obtained from cats. A second objective was to identify factors that contributed to changes in the dimensions of tissue obtained from normal cats that underwent routine histological processing. Cutaneous and Myocutaneous samples were obtained from twelve normal cats at three locations, the neck, thorax and tibia. Dimensional measurements of the samples were taken at five time points by a single observer. The time points included prior to excision, after excision, after margins were inked, 36 hours after fixation in formaldehyde and after completion of histological processing and hemotoxylin and eosin staining. The measurements at each time point were compared to original measurements at the first time point.

Tissue samples decreased in lateral margins and increased in depth at the final time point. The average shrinkage in the lateral dimensions was $35 \%$ and the increase in depth was $55 \%$. The tibia exhibited the greatest shrinkage and the neck exhibited the least shrinkage. Inclusion of the underlying muscle did not affect the degree of change in dimension of the specimen.

In the present study, each element from excision to formalin fixation and histopathological processing induced changes in tissue dimension manifest principally as shrinkage in the lateral margins and an expansion of the depth. Shrinkage should be a consideration when interpreting surgical margins in clinical cases. Further investigation of this phenomenon in a wider feline population in clinical cases is warranted to classify

the degree of change in dimensions of specimens and to identify other variables that affect the degree of tissue shrinkage.

## Acknowledgements

I would like to express my gratitude to Dr. Henderson for conceptualizing this research question and assisting in the design and execution of this project. I would also like to thank Dr. Tillson, Dr. Smith and Dr. Schleis and Dr. Cattley for their assistance with the design and execution of this study. Their patience, guidance and expertise in their respective specialties have allowed the successful completion of this project.

A special thanks goes to Dr. Dillon for allowing the use of cats from a previous study. I would also like to thank Sharon Barney and Cynthia Hutchinson for their help and patience with this project. Also, I would like to acknowledge Dr. Wright for his assistance with statistical analysis.

I would also like thank my family, who have supported me throughout the entire process.

## I. INTRODUCTION

Surgical excision is the mainstay of treatment for primary skin neoplasia in cats.
Definitive oncologic surgical treatment only requires removal of all neoplastic tissue. However, since the leading edge of the neoplasm is microscopic, the precise edge of an ideal excision cannot be seen. For this reason, the gross neoplasm is removed with additional normal appearing tissue. Since the leading edge of the neoplasm may not uniformly invade the surrounding tissue, the surgical margin is evaluated in the microscopic assessment of the submitted specimen after histological processing to estimate whether it is probable that the entire neoplasm was removed.

The margin status is considered one of the most important components of the veterinary pathology report and is an important prognostic indicator for local disease recurrence and progression. ${ }^{1-6}$ In cases where neoplastic cells extend close to the surgical margins, the margins should be quantified based on the smallest distance. The quantification of the surgical margin is directly influenced by the phenomenon of specimen shrinkage.

In humans, specimen shrinkage is a widely acknowledged phenomenon that occurs in tissues that are excised and then undergo histologic processing. ${ }^{7-18}$ In an effort to better understand the relationship between in vivo margins and final histopathological margins, there has been investigation of the causal factors into specimen shrinkage. Factors including the tissue type, tissue location, age of the patient, and type of histological processing have been identified to influence the degree of shrinkage. ${ }^{7,8,12,14,16}$

Currently, there is limited information on specimen shrinkage in dogs, and no information in cats. ${ }^{19}$ Therefore, interpretation of surgical margins is limited to what can be extrapolated from other species. Due to differences between feline skin and human and canine skin, the extent of tissue shrinkage may be different in this species. ${ }^{20-22}$ Specifically there are denser and coarser collagen bundles and larger arector pili muscles. ${ }^{21}$ Additionally in the cat, the dorsal neck and scapular regions are constituted by smaller more loosely arrange collagen bundles, which allow greater skin elasticity. ${ }^{22}$

The objective of this study is to investigate the nature of feline tissue shrinkage as it occurs in cutaneous and myocutaneous specimens that undergo routine histological processing. Furthermore, we will identify the time points during histological processing where specimen shrinkage occurs by repeatedly measuring the specimens throughout the entire process from prior to surgical excision to final histopathological measurement and whether other factors such as topographic site or the inclusion of underlying muscle influence the degree of specimen shrinkage.

## III. LITERATURE REVIEW

Assessment of Surgical Margins
Examination of surgical margins is based on representative samples (standard size is 5 $\mu \mathrm{m}$ for each section) taken by the pathologist. ${ }^{23,24}$ The selection of representative samples is an important factor as a potential source of error for margin evaluation. Optimally, the surgeon would have identified high risk or high interest areas. The pathologist will sample these sites as well as a more general sectioning of the tissue; a process referred to as "cutting in" the tissue, using one of several techniques including cross sectioning (Figure 1), breadloaf technique (Figure 2), breadloaf cross sectioning (Figure 3), peripheral sectioning (Figure 4) and Moh's oblique sectioning (Figure 5). ${ }^{23}$ Two of the more common techniques used in veterinary pathology are cross sectioning and breadloaf technique. ${ }^{24}$

## Cross Section Technique

Figure 1. Cross Section, or Cruciate Technique - A section is taken through the short axis of the specimen. A second section is taken at 90 degrees to the short axis, in the long axis of the section. These tissues are further processed for microscopic evaluation.

## Breadloaf Technique

Figure 2. Breadloaf Technique - Serial sections are taken are taken at 90 degrees to the long axis of the specimen. These tissues are further processed for microscopic evaluation.

## Breadloaf Cross Section Technique

Figure 3. Breadloaf Cross Section Technique - A section is taken in the plane of the long axis of the specimen, and then sequential sections are taken at 90 degrees to the long axis of the specimen in the area of diagnostic interest. These tissues are further processed for microscopic evaluation.

## Peripheral Section Technique

Figure 4. Peripheral, or Perimeter or En face Section Technique- Sections are taken from the periphery of the specimen. The cut surface is placed face down on the cassette. This surface will approach the microtome blade. This orientation of the cut surface allows the pathologist request deeper levels of the block to reach the true tumor-free margin. These tissues are further processed for microscopic evaluation.

## Moh's Oblique Section Technique

Figure 5. Moh’s oblique or En Face Oblique Section Technique - The tumor is removed with oblique ( 45 degree) lateral margins. The specimen is flattened such that the lateral and deep margins are on the same plane and frozen. Microtome sections are then taken in this plane to analyze both the lateral and deep margins simultaneously. If there is evidence of tumor infiltration at this margin, further sections of tissue are taken from the tumor bed.

For Cross sectioning the specimen is sectioned in two planes, 90 degrees to the long axis and then each half is bisected again at 90 degree to the first cut, to create quarters. A slice of tissue is then taken from each of these segments and is further processed prior to evaluation. ${ }^{24}$ This technique assumes the tumor is growing symmetrically and is centrally located within the specimen ${ }^{23}$ The breadloaf technique involves transversely sectioning the tissue specimen at different intervals ${ }^{24}$ The main disadvantage of all techniques is the
relatively small amount of tissue evaluated compared to the volume of the submitted tissue (approximately $1 \%$ ) and therefore inaccuracies in interpreting the margin status of the excised specimen may be introduced ${ }^{23,24,25}$

To help guide histopathological assessment, the foci of interest can be identified by the surgeon. First, the entire surgical margin may be identified using an adhering marker (latex paint or India's artist ink) to paint the cut surface of the excised tissue to facilitate the assessment of surgical margins by the pathologist. ${ }^{24,25}$ Painting the excision margin facilitates distinguishing the true margin and artifactual processing margins created when the tissue is trimmed. Additionally, the surgeon may identify and paint one or more margins of an excised specimen with different colors to permit orientation of the specimen. Finally, the surgeon can identify high risk foci as judged at surgery by placement of suture tags or unique color markers. In combination with a diagram and written description these methods maximally assist the pathologist as the submitted specimen is sectioned for histopathological assessment.

In cases where neoplastic cells extend close to the surgical margins, the margins may be quantified based on the smallest distance from the marker to the neoplasm's leading edge. The pathology report should describe neoplastic cells, the tissue constituents, tissue quality closest to the margin, and an objective measurement of the margin. ${ }^{24}$ The definitions of close or narrow margins should be avoided, as there is no consensus on the objective classification of close or narrow margins in veterinary medicine.

A major source of error in margin determination is tissue shrinkage. Tissue shrinkage is the decrease in dimensions of the tissue following surgical excision and histological processing. Tissue shrinkage is a well- acknowledged phenomenon that occurs following surgical excision and specimen processing. ${ }^{8-18}$ The magnitude of tissue shrinkage in a given specimen will directly influence the measurement of the surgical margin reported by the pathologist. Quantification of tissue shrinkage is clinically important in interpreting the histopathological tumor-free margin as this will determine the factor by which this differs from the true in vivo tumor-free margin. For a given neoplasm, the final histopathological margin can be translated back to the true margin in vivo, which can be correlated with the risk of recurrence and outcome.

The focus of previous studies investigating tissue shrinkage has been to identify the main cause of tissue shrinkage and to reliably predict the amount of shrinkage that occurs following excision and processing. The fundamental causes of specimen shrinkage that were identified are twofold. Firstly, the retractile properties of tissue lead to shrinkage prior to fixation. ${ }^{8,12,14}$ Secondly, specimen processing further causes shrinkage of specimens. ${ }^{7,8,12,16}$ There was a debate as to whether the majority of shrinkage occurs after surgical excision and prior to formaldehyde fixation or after histopathological processing.

Recent papers identify the majority of shrinkage to occur prior to fixation ${ }^{812,14}$ In excised skin specimens, $70-100 \%$ of total specimen shrinkage occurred after skin excision and prior to fixation. ${ }^{7,12}$ The shrinkage post-excision is attributed to intrinsic contractile
properties of the tissue itself. ${ }^{14}$ The retractile properties of human skin specimens have been further investigated. ${ }^{15}$

In one study, in vivo thickness of the specimen was measured using ultrasound and compared to the ex vivo measurement. A significant increase in thickness was found to correspond to the decrease in the width and length of specimen, suggesting that the specimen retracted following excision ${ }^{15}$ The amount of contraction and therefore shrinkage is dependent on the component tissues included in the specimen.

Intuitively it would seem that the mechanical properties of the tissue relating specifically to the collagen and elastin content would influence the contraction and shrinkage of the specimen. However, this has yet to be unequivocally proven. ${ }^{7}$

Patient factors such as the patient's age can indirectly affect tissue shrinkage due to the influence on inherent tissue contractility. However, there is little consensus amongst human studies as to whether age significantly affects specimen shrinkage, as most studies using cut off points of 50 or 60 years, not able to find an association. ${ }^{7,8,14}$ Furthermore, the clinical significance of a small association between increasing age and decreasing specimen shrinkage is unknown.

In addition to the inherent qualities of skin, other factors can play a role in specimen shrinkage, including tumor-related factors such as specimen size and location. Specimen size can affect the magnitude of shrinkage with larger specimens having a relatively
lower amount of shrinkage. ${ }^{8,12}$ An inverse relationship exists between the initial length and depth and the degree of shrinkage of the specimen ${ }^{8}$ Topographic location of the lesion is another important determinant of the extent of tissue shrinkage. Tissue located on the limbs is more likely to shrink when compared with those of the head and neck. ${ }^{14}$ This is most likely associated with the relative elasticity and inherent contractility of the tissue after excision.

Early studies assumed tissue shrinkage was uniform across the entire specimen. Day and Lew estimated that the original margin could be calculated by applying a $25 \%$ shrinkage factor to cutaneous specimens that are excised and processed. ${ }^{26}$ Goldstein reported doubling the final processed margin length to estimate the in vivo margin. ${ }^{11}$ However, recent data suggests that non-neoplastic tissue may shrink more than neoplastic tissue. Blasdale identified a differential shrinkage between normal tissue, which had mean shrinkages of $19 \%$ and by $11 \%$, respectively. ${ }^{7}$ Similarly, Hudson and Peacock detected an $8 \%$ difference in the amount of shrinkage between benign and malignant tumors. ${ }^{13}$ This is hypothesized to occur due to the inflexible structure of tissue protein, lipid and water in neoplastic tissue, which allows the tissue to retain the original shape. ${ }^{7}$ Therefore calculations that are based on a derived formula or shrinkage factor may underestimate the magnitude of the in vivo tumor free margin.

The problem of non-uniform reduction in tissue shrinkage at the transition zone of neoplasm-normal tissue was further highlighted when margins of breast cancer surgery were assessed. ${ }^{18}$ The tumor shrinkage (4\%) was significantly lower than adjacent non-
neoplastic tissue (34\%). The explanation the authors offered was suggested the possibility of degradation of lipids by formaldehyde during the fixation process, leading to greater shrinkage of the non-neoplastic tissue, which has a higher fat content. Once again this highlights how reported margins may be spuriously lower than the in vivo margin.

## Current Veterinary Literature

There is limited information on tissue shrinkage following excision from canine or feline specimens. Although pathologists accept that this phenomenon does occur in canine and feline patients, the majority of this information has been extrapolated from the human literature. ${ }^{24}$

One study investigated the effect of routine processing on tissue specimens from dogs. In this study a significant decrease in specimen width and length was evident and similar to the human studies, there was an increase in specimen depth. The cause of this change was attributed to tissue processing. Samples that consisted of skin and subcutaneous tissue had a greater degree of shrinkage compared to samples that also contained muscle. ${ }^{19}$

Few studies have investigated the histological assessment of surgical margins in dogs. These studies have investigated the relationship between histopathological margins and recurrence of cutaneous mast cell tumors. ${ }^{2,4,6}$ In these studies close margins were defined as those $\leq 1 \mathrm{~mm}$. This was an arbitrary cut off point, and there is no data to indicate a histological margin of $\geq 1 \mathrm{~mm}$ is a complete margin. In contrast, a similarly designed study on a cohort of dogs with mast cell disease found lateral margins that exceeded
$\geq 10 \mathrm{~mm}$ and deep margins that exceeded $>4 \mathrm{~mm}$ had no evidence of recurrence. ${ }^{5}$ These numbers resulted from measuring processed tissues so the quantity of tissue that is needed to be harvested as the original margin is not correlated and the exact preoperative measurement required for clean or close margin remains unclear.

Additionally, definitions of margin status will vary with tumor type and behavior. In a study on cutaneous tumors in dogs and cats, which consisted of three cutaneous tumor types including soft tissue sarcoma, mast cell tumors and carcinomas, there was a difference in the accuracy of a $<2 \mathrm{~mm}$ margin to predict the likelihood of recurrence in each tumor type. ${ }^{27}$ The data from this study indicated that there was a $76-94 \%$ correlation between margin classification (dirty or close vs clean) and recurrence of tumor. However, the variability of tissue shrinkage and its influence on the final measurement of the tumor free margin, and therefore the risk of recurrence remains unknown in cats.

## Conclusions

Current understanding of tissue specimen shrinkage recognizes that the majority of shrinkage occurs following excision. Specimen shrinkage is attributed to the retractile properties of the tissue that result in shrinkage of the length and width of the specimen, and may result in a marginal increase in the depth of the specimen. Although formulas have been developed to predict the in vivo measurements, discrepancies between the relative shrinkage of tumor vs non-tumor tissue within a specimen may be introduced by pre-processing marking, processing artifact, topography and relative content of neoplasm. Such factors may falsely decrease or increase the size of the surgical margin calculated.

There is currently little data in the veterinary literature that allows the pathologist to accurately predict the amount of shrinkage that occurs from surgical excision to final histopathological assessment of surgical margins. This presents a dilemma for the clinician in interpreting surgical margins and advocating further treatment recommendations.

## III. MATERIALS AND METHODS

## Animal Subjects

Twelve adult cats with a body condition score of 4 to 6 (on a scale of 1 to 9 ) were included in the study. Cats were obtained upon euthanasia after completion of another unrelated study. The skin and underlying tissues were not disturbed in the regions of sample collection. Cats weighed between $2.4-4.8 \mathrm{~kg}$ (mean $=3.27 \mathrm{~kg}$ ). On physical examination prior to euthanasia, cats were free of any grossly apparent dermatological disease.

Skin Sample Collection
Cats were placed in lateral recumbency and six areas were routinely clipped. Skin samples were obtained from three sites bilaterally (6 samples/cat Figure 6). The sites determined for sampling were the lateral aspect of the neck, lateral aspect of the thorax, and the proximolateral aspect of the tibia. The samples collected from the neck were centered over a point equidistant between the point of the scapula and the wing of the atlas. The samples collected from the lateral thorax were centered over a point 5 cm caudal, and at the level of the point of the elbow. The samples collected from the tibia were 2.5 cm caudal at the level of the tibial tuberosity.

Figure 6. Illustration of sites (lateral neck, lateral thorax, proximolateral tibia) of specimen collection. Specimens were collected bilaterally in 12 cats ( 6 samples/cat).

All samples were elliptical and orientated in the diagram (Figure 6). The samples collected from the neck and tibia measured $80 \mathrm{~mm} \times 40 \mathrm{~mm}$ in the craniocaudal and dorsoventral plane, respectively. The samples collected from the lateral thorax measured $120 \mathrm{~mm} \times 60 \mathrm{~mm}$ in the craniocaudal and dorsoventral plane, respectively. The deep plane was taken to include dermis and subcutaneous tissue and fascia. In the samples collected from the lateral thorax, the left or right side was randomly assigned, by coin toss, to include the underlying latissimus dorsi.

A plastic template was used to draw the ellipse over each location using a surgical skin marker (Devon Surgical Skin Marker, Covidien, Mansfield MA). The skin was incised with a No. 10 scalpel blade. The initial skin incision was made to the desired depth in one section to allow the depth to be measured prior to contraction of the specimen. The desired depth was to the level of the fascia in the neck and tibia locations. In the thorax
location, the desired depth was at the level of the fascia or included latissimus dorsi. The tissue was then undermined and the excision was completed by incising the skin, subcutis and muscle (where indicated) with Metzenbaum scissors.

## Measurements

The tissues were measured and recorded in triplicate to the nearest 1 mm using a ruler (Devon Skin Marker Ruler, Covidien, Mansfield MA) by a single observer and the mean was calculated. Once the specimen was excised, one drop of tissue ink (Margin Marker, Vector Surgical, Waukesha, WI) was used to mark the cranial, caudal, dorsal and ventral aspects of each skin sample. This allowed future orientation and identification of each margin and served as a repeatable point of measurement. The color selected for each region was standardized for consistent orientation during subsequent measurements. Specifically, the tissue ink was used to mark the cranial margin yellow, the caudal margin red, the dorsal margin blue and the ventral margin green.

The measurements included cranial to caudal distance (length) and the dorsal to ventral distance (width) and the distance from the surface of the skin to the level of the deepest tissue layer excised (depth).

The measurements were sequenced in the following manner: Once the proposed incision was marked measurements of the length and width were taken (time point, T1). After the skin incision was made to the desired depth, the depth measurement was taken (time point, T1). After completion of excision, samples were placed on a flat glass surface with
$1-2 \mathrm{~mL}$ of sterile saline added to reduce surface tension and then the dimensions were measured (time point, T2). The sample was then inked, and 10 minutes was allotted for drying, prior to completing the third measurements (time point, T3). Samples were then placed in $10 \%$ neutral buffered formaldehyde that was approximately 10 times the sample volume for 36 hours. Following formaldehyde fixation, measurements were then taken (time point, T4). Final measurements were taken after completion of routine histological processing with standard paraffin embedding and hemotoxylin and eosin staining (time point T5). Each slide was scanned, and measurements were taken using digital pathology software (Visiomorph DP, Visiopharm, Denmark) by the same observer (Figure 7).

Figure 7. Measurement of skin sample at T5. The slide was scanned and the dimensions were measured digitally using software (Visiomorph DP).

Data recorded included 3 measurements (length, width and depth) at 6 anatomical sites (lateral neck, lateral thorax and proximolateral tibia bilaterally) at each of the 5 time
points. Each data set was compared to the original measurements based on percentage change recorded as a positive or negative.

## Statistical Analysis

The data was analyzed using Statistical Analysis System (SAS, Version 9.3, Cary, NC), and the mixed model for repeated measures analysis to evaluate the effects of anatomical site, time point and dimension was employed. The effect of time point on skin specimen dimensions was assessed using least means square test for multiple comparisons. The effect of location was evaluated between samples from the neck, lateral thorax (without the inclusion of the underlying muscle) and proximal tibia after normalizing data to the original size using the Scheffe's test for multiple comparisons. The effect of including a muscle layer was determined via comparisons of samples from the lateral thorax using the Scheffe's test for multiple comparisons. Values of $\mathrm{P}<0.05$ were considered significant.

## IV. RESULTS

## Animal Subjects

Skin specimens were obtained from twelve cats at three locations bilaterally (total of 72 samples). All cats were 14 months of age and were female. Cats had a mean weight of 3.27 kg , and a mean body condition score of $4 / 9$. There were no dermatological conditions noted on physical examination.

## Measurements

Effect of Time
There was a significant decrease in the length and width of skin specimens from T 1 to T 5 $(\mathrm{P}<0.001)$. There was also a significant increase in the depth from T 1 to T 5 at the lateral thorax, tibia and neck locations ( $\mathrm{P}=0.0116, \mathrm{P}<0.001$, respectively)

Change in original Length (\%) of specimens vs time

Figure 8. Graph of the change in length (\%) of the skin specimens over time. The x -axis represents the time points, and the $y$-axis represents the change in length as a percentage of the original dimension in vivo.

Change in Length of specimens from original dimension (\%)

| Location | T2 | T3 | T4 | T5 |
| :---: | :---: | :---: | :---: | :---: |
| Lateral | -5.9 | -9.0 | -14.5 | -32.7 |
| Thorax |  |  |  |  |
| Neck | -7.2 | -12.4 | -12.4 | -33.8 |
| Tibia | -11.1 | -15.6 | -15.6 | -39.3 |

Change from original Width (\%) of specimens vs. time

Figure 9. Graph of the change in width (\%) of the skin specimens over time. The x -axis represents the time points, and the $y$-axis represents the change in width as a percentage of the original dimension in vivo.

Change in Width of specimens from original dimension (\%)

| Location | T2 | T3 | T4 | T5 |
| :---: | :---: | :---: | :---: | :---: |
| Lateral | -15.1 | -16.4 | -18.4 | -30.3 |
| Thorax |  |  |  |  |
| Neck | -13.7 | -14.2 | -15.5 | $-30,0$ |
| Tibia | -28.0 | -29.0 | -30.9 | -46.2 |

Change in original Depth (\%) of specimens vs time

Figure 10. Graph of the change in depth (\%) of the skin specimens over time. The x-axis represents the time points, and the y-axis represents the change in depth as a percentage of the original dimension in vivo.

## Change in Depth of specimens from original dimensions (\%)

| Location | T2 | T3 | T4 | T5 |
| :---: | :---: | :---: | :---: | :---: |
| Lateral | -15.9 | -15 | -13.1 | +27 |
| Thorax |  |  |  |  |
| Neck | -6.9 | -8.3 | -8.3 | +62.3 |
| Tibia | -8.1 | -14.1 | -22.2 | +75.8 |

## Effect of plane

The magnitude of decrease in the width of specimens was greater than the magnitude of decrease in length, at time point T 2 through $\mathrm{T} 4(\mathrm{P}<0.001)$. However, at time point T 5 , there was no difference in the magnitude decrease in width compared to length of the skin specimens $(\mathrm{P}=0.5849)$. The change in size of skin specimens in the depth plane was different from the width plane at time points T 2 through $\mathrm{T} 5(\mathrm{P}<0.001)$. The amount of change in size of specimens in the depth plane was only different from the length plane at T5 ( $\mathrm{P}<0.001$ ).

## Effect of Location

The neck, lateral thorax and tibia locations exhibited different magnitude of change in width and length at time points $\mathrm{T} 3, \mathrm{~T} 4$ and $\mathrm{T} 5(\mathrm{P}=0.413, \mathrm{P}<0.001, \mathrm{P}<0.001)$ but not at $\mathrm{T} 2(\mathrm{P}=0.0789)$.

On pair wise comparison of the magnitude of decrease in length and width, the specimens of the neck and tibia were significantly different at $\mathrm{T} 3, \mathrm{~T} 4$ and $\mathrm{T} 5(\mathrm{P} 0.0422, \mathrm{P}<0.001, \mathrm{P}=$ 0.013). However, there was no significant difference between the magnitude of shrinkage on the neck compared to the lateral thorax.

## Effect of Inclusion of Underlying Muscle

Change of Skin Specimen from original size (\%)

| Location | Plane | T1-T2 | T2-T3 | T3-T4 | T4-T5 |
| :--- | :--- | :---: | :---: | :---: | :---: |
| Lateral Thorax | Length | -5.9 | -9.0 | -14.5 | -32.7 |
| Lateral Thorax - inclusion of muscle |  | -13.4 | -16.7 | -16.7 | -35.5 |
| Lateral Thorax | Width | -15.1 | -16.4 | -18.4 | -30.3 |
| Lateral Thorax - inclusion of muscle |  | -17.9 | -18.7 | -20.2 | -32.2 |
| Lateral Thorax | Depth | -15.9 | -15 | -13.1 | +27 |
| Lateral Thorax - inclusion of muscle |  | -10.6 | -8.0 | 6.2 | +22.2 |

There was no difference in the depth or width of skin samples at time points T1-T5 skin samples that included the underlying muscle compared to control on the lateral thorax (see table below). There was a significant difference in the length measurement at T 2 between skin samples that included the underlying muscle compared to the control. At
time points T1, T3-T5, there was no difference in the length measurement between skin samples that included the underlying muscle compared to control.

Geometric Least Means Procedure for comparison between Lateral Thorax samples and Lateral thorax with underlying muscle samples

| Plane | Time Point | Difference between <br> Means | Simultaneous 95\% Confidence <br> Interval |
| :---: | :---: | :---: | :---: |
| Depth | T1 | -0.1667 | $(-0.8127,0.4693)$ |
|  | T2 | -0.3056 | $(-0.8844,0.2733)$ |

|  |  |  | $\left(\begin{array}{l}\text { T5 } \\ \end{array}\right.$ |

* Denotes statistical significance

## V. DISCUSSION

The present study confirms there were substantial alterations in dimensions of skin samples following excision and histological processing in cats. This study was closely modeled on the canine study to allow for comparisons. Similar to the canine study, there was a decrease in size of skin samples in the length and width dimensions and an increase in the depth dimension. ${ }^{19}$ The underlying cause of this effect could be associated with the excision and manipulation of tissues and the inherent retractile properties of skin. ${ }^{8,12,14}$ Additionally, dehydration of the specimen with immersion in alcohol and the fixation process may lead to further changes to the structure of the skin sample. ${ }^{7,12,16}$

The length and width of the skin specimen, otherwise known as the lateral margins, decreased on average by $35.3 \%$ and $35.5 \%$, respectively, following excision and histological processing. However, the depth of the skin specimen on average increased by $55 \%$. This is similar to the trend reported in dogs, where the length and width decreased by $26.5 \%$ and the depth increased by $65.3 \%$ (Reimer, $A m J$ Vet Res 2005). The decrease in length and width of skin specimens is consistent with similar studies in humans, where normal lateral margins decreased in size between 15-25\% of the original dimension. ${ }^{7,12,16}$ However, the increase in the depth of tissue measured has not been consistently found in humans.

The depth measurement in the present study was made similar to the other measurements. It was difficult to accurately measure the depth in situ prior to completion of the excision.

The measurement at T 1 was used then to calculate the decrease from original dimensions, and therefore could have been a source of measurement error, and the calculation of overall change in each time point thereafter. However, it is still plausible that the specimens retracted in the lateral dimensions and increased in depth after histological processing. This finding was also noted in the canine study, where the specimens were thicker in the depth plane whilst smaller in the width and length planes ${ }^{19}$ This may be due to removal of water, lipids and alterations in the structure of cell proteins by the fixation and dehydration process that may have caused the epidermis, dermis, subcutaneous structures and underlying muscle to separate. ${ }^{28}$

In clinical cases, the measurement of tumor depth and the surgical margin in this plane is interpreted alongside the presence of a fascial plane. The presence of fascia may act as a biological barrier in some cases and is therefore is evaluated in the determining the completeness of excision. ${ }^{29}$ In the current study, the margin in the depth plane increased following excision and processing compared to the in situ margin. The over estimation of this margin is a consideration when interpreting the reported depth margin in the histopathology report. However, this should be combined with the assessment of the presence of one or more fascial planes present in the surgically excised tissue.

The neck, lateral thorax and tibia were chosen as locations, to allow comparison to the canine study as well to represent three distinct locations. The tibia had a significantly greater amount of shrinkage compared to the neck, in the lateral dimensions at time points T3-T5. The lateral thorax was intermediate in the amount of shrinkage, similar to
the canine study ${ }^{19}$ This finding in the present study is consistent with other human studies that have shown that the extremities exhibit a greater amount of shrinkage compared to the trunk. ${ }^{13}$ In humans this is thought to be due to the inherent contractility of tissue after excision. ${ }^{14}$ However, this theory is less plausible in the present study where the T4 and T 5 time points exhibited the greatest difference, rather than the T 2 time point, suggesting that the tissues from the tibia underwent a greater degree of shrinkage during the crosssectioning, fixation, dehydration, microtomy, embedding and staining.

The long axis of the ellipse was oriented in the craniocaudal plane. This was opposite to the lines of tension in the neck and lateral thorax location. ${ }^{30}$ Although this does not typically mimic the clinical situation, this orientation was chosen to compare results to the previously reported canine study. In the canine study, the majority of the total shrinkage occurred in the plane of tension, since the short axis was orientated in the plane of tension. ${ }^{19}$ However, in the present study, the total shrinkage in both planes was similar, suggesting that the plane of tension did not influence the magnitude of shrinkage.

The majority of changes occurred between T4 and T5. Specimens were cross-sectioned, placed in alcohol solution, embedded in paraffin and microtome sectioned, mounted on the slide and stained with hemotoxylin and eosin. These steps are responsible for the majority of changes to the specimens in the present study. The dehydration process where tissues are immersed in alcohol can lead to rapid removal of water from the specimen, which correlates with the degree of shrinkage ${ }^{28}$ In the present study, the specimens were placed in gradually increasing concentration of alcohol fixative for a fixed time period
that had been previously calibrated for the automated processor. Additionally, the embedding of specimens in paraffin is performed at a higher temperature, which affects the structure of collagen and leads to distortion and shrinkage of the specimen. ${ }^{31}$

The inclusion of the underlying muscle at the lateral thorax location did not influence the alterations in dimensions. This finding is surprising, given the canine study showed that inclusion of the underlying muscle reduces specimen shrinkage. One explanation could be a type 2 error in this study, however, given the larger sample size in this study this is unlikely. In the canine study, Labradors were chosen, with a larger amount of subcutaneous tissue and a more robust cutaneous trunci and latissimus dorsi muscle; it is likely that the depth of this sample compared to the control group was greater. In the present study, cats were of moderate body condition, however the cutaneous trunci and latissimus dorsi are relatively thinner, and therefore the influence of these muscle on the magnitude of shrinkage may have been smaller.

In the present study a scalpel blade and scissors were used to excise the tissue. Other modalities such as cutting diathermy, coagulation diathermy, carbon dioxide laser, or harmonic scalpel may be used to excise the cutaneous neoplasm. These techniques have been known to induce cellular damage, including condensation, hyalinization and loss of fibrillar texture of collagen, at the surgical margin. ${ }^{32}$ Additionally, the thermally induced contraction of collagen resulted in irregular shrinkage patterns. ${ }^{32}$ In a previous study investigating different cutting modalities, cutting diathermy produced the cleanest cut with the least amount of shrinkage. ${ }^{33}$ Comparatively the scalpel produced the greatest
amount of shrinkage. ${ }^{33}$ Therefore, this data may not be extrapolated in clinical cases where other methods were employed during the surgical excision.

## Study Limitations

The present study has some limitations. Firstly, the study involved a small number of cats that are not representative of the wider feline population. The age, breed and size were homogenous. Extrapolating this data to other cats may not be accurate. Different breeds, particularly with different skin elasticity (for example, the Devon Rex) may experience a variation in skin shrinkage during histological processing. Additionally, patients that are more likely to have neoplastic conditions may be older, and may experience a different degree of skin shrinkage. In humans, patients older than 60 years of age had decreased shrinkage compared to patients that were younger. ${ }^{16}$

The study was performed in recently euthanized cats. All skin samples were collected within 30 minutes of euthanasia. Although unlikely to influence the degree of shrinkage, there may have cell autolysis and decomposition, which may influence the degree of skin shrinkage. Following death, the dermis and epidermis do not undergo any histological alterations in the first 6-8 hours. ${ }^{34}$ Furthermore, in the present study there was no evidence of cell autolysis on evaluation of the specimens at T 5 .

Another source of error is the standardization of tissue sample collection and measurement. Distortion of the skin during was minimized by using a template to draw the proposed skin incision. Additionally, skin samples were manipulated minimally
during the collection and measurement. To eliminate interobserver error the samples were measured by a single observer. The observer was not blinded to the treatment, and this remains a potential source of bias.

Although the study was conducted in cats with normal skin that were free of dermatological conditions, the data can be extrapolated to patient with neoplastic conditions of the skin, considering that the tissue of interest when assessing and measuring the surgical margin should be non-neoplastic tissue. However, it is possible to have inflammation surrounding neoplastic tissue, which may exhibit a variation in the pattern of shrinkage.

## VI. CONCLUSION

The purpose of this study was to evaluate any changes to the size of skin specimens that underwent excision and routine histological processing in cats and to compare these changes to those reported in the dog. To the extent practical, the methods used were to duplicate the dog study. The findings of these two studies were similar with differential magnitudes. The lateral dimensions decreased the depth of specimens increased from each site: the neck, lateral thorax and proximal tibia. A greater amount of change from the original dimensions was noted in the specimens from the proximal tibia. Although changes occurred following excision, most of the changes to the dimensions of samples occurred following processing including the steps of dehydration, microtome sectioning, paraffin embedding and rehydration. The magnitude of decrease in dimensions in the lateral margins is in the order of $35 \%$ and the magnitude of increase in depth dimensions is in the order of $55 \%$. Although this data may help guide interpretation of surgical margins in cats, further investigation of this phenomenon in clinical cases in a wider population of cats is required.
