## VITA

Heather Gray Edwards, daughter of Timothy Shawn Gray and Jennifer Anne Gray, was born December 7<sup>th</sup>, 1980 in Phoenix, Arizona. She graduated from the University of Arizona, in Tucson, Arizona with a Bachelor of Science in Microbiology in August, 2003. In the spring of 2003, she was awarded the BRAVO fellowship and studied in Madrid, Spain at the Consejo Superior de Investigaciones Científicas under the guidance of Dr. Sebastián Cerdán. In the fall of 2003, she was granted a fellowship as a graduate student in the Department of Cellular and Molecular Biology in the College of Science and Math at Auburn University, Auburn, Alabama. In fall 2004 she joined the Department of Anatomy, Physiology and Pharmacology in the College of Veterinary Medicine as a graduate teaching assistant under the guidance of her mentor, Dr. Dean Schwartz. She is married to Michael Edwards, son of Robert Patrick Edwards and Jacklyn Barrett Edwards.

DISSERTATION ABSTRACT  
PROTECTION FROM OXIDATIVE STRESS IN THE CARDIAC  
H9C2-CELL LINE BY THE TRANSCRIPTION FACTOR NRF2

Cardiovascular disease (CVD) is the leading cause of death in the United States, and its prevalence is increasing in all populations and age groups worldwide (71). In 2002 alone, more than 927,000 Americans died from heart disease-related conditions. Oxidative stress, or the generation of reactive oxygen species (ROS), is a contributing factor to the progression of many cardiovascular diseases. One approach to combat the detrimental effects of oxidative stress in cardiac disease is to use the cell's inherent ability to increase the expression of various stress-related proteins to eliminate the oxidative stress. NF-E2 related factor 2 (Nrf2) is the transcriptional activator of the antioxidant response element (ARE) found in the promoter region of antioxidant and phase II detoxifying genes. In this study, we examined the role of Nrf2 in protecting the H9c2 cardiac-like cell line against oxidative stress. Nrf2 was induced using the known Nrf2 activator *tert*-butyl hydroquinone (tBHQ). We measured heme oxygenase-1 (HO1)

and NAD(P)H:quinone oxidoreductase 1 (NQO1) gene and protein expression as markers of ARE-driven gene activation in response to tBHQ. We also determined ROS generation using the fluorescent probe carboxy-H<sub>2</sub>DCFDA, and cell viability in response to the prooxidants *tert*-butyl hydroperoxide (tBHP) and H<sub>2</sub>O<sub>2</sub> in the presence and absence of activated Nrf2. To directly evaluate the roles of Nrf2 and its inhibitory protein Keap1, we utilized Nrf2 and Keap1 siRNAs to knockdown Nrf2 and Keap1 expression. H9c2 cells overexpressing Nrf2 tagged with either green fluorescent protein (GFP) were also generated to examine Nrf2 localization using fluorescent microscopy and gene expression of ARE-containing genes.

In H9c2 cells tBHQ activated Nrf2 resulting in the translocation of Nrf2 into the nucleus and increased the transcription and translation of the ARE-driven genes HO1 and NQO1. The prooxidant, tBHP increased ROS generation and cell death in H9c2 cells and pretreatment with tBHQ abrogated both these effects. Nrf2 knockdown experiments resulted in a blunted induction of tBHQ-induced HO1 and NQO1 expression and a loss in the protective effect of tBHQ on tBHP-induced ROS generation. Cell death in response to tBHP and H<sub>2</sub>O<sub>2</sub> was augmented in cells treated with Nrf2 siRNAs, but rescued by Keap1 knockdown. H9c2 cells overexpressing Nrf2-GFP displayed fluorescence that was sequestered in the cytoplasm and translocated to the nucleus upon treatment with tBHQ. Along similar lines, HO1 and NQO1 gene expression remained at basal levels, despite Nrf2 overexpression and cytoplasmic localization. HO1 and NQO1 gene expression was enhanced in Nrf2 overexpressing cells after tBHQ treatment. From these studies, we conclude that Nrf2 protects the cardiac-like H9c2 cells from oxidative stress.

## ACKNOWLEDGEMENTS

I would like to express my gratitude to those in Auburn University's College of Veterinary Medicine, its Dean Boosinger, the Associate Dean of research Dr. Pinkert, as well as those in the Department of Anatomy, Physiology and Pharmacology and its Department Head Dr. Morrison for the opportunity to attend graduate school at Auburn University. I would also like to thank the Molecular and Cellular Biosciences Program and Kathy Feminella and Dr. Bartol for support throughout my graduate career. I would like to express my deepest appreciation to my mentor and major advisor, Dr. Schwartz, for his support and guidance. Without him, none of this would have been possible. I would also like to thank the members of my committee, Dr. Ellis, Dr. Judd, Dr. Kemppainen and Dr. Sartin for all their help planning and executing this project. For their assistance in the laboratory and friendship during this work, I would like to thank Colin Rogers, Dr. Chancey, Dr. Clarke, Dr. Bedi, Dr. Brunson, Zhechuan Fan, Dr. Ahluwalia, Kathy O'Donnell and Barbara Steele. I would also like to thank Debbie Allgood, Hattie Alvis, Diane Smith, Dorothy Spain, Bobby Meadows and Mary Lloyd for all their help and support. I would also like to express my profound appreciation to my family, Timothy Gray, Tyler Gray, Jennifer Gray and Sharon Graham for their love and support. Most of all, I would like to thank my husband, Mike Edwards, for his level-headedness and endless support during this process.

## INTRODUCTION

Cardiovascular disease is the number one killer in the United States. Four to five million Americans currently have heart failure, and it is estimated that the number of heart failure patients will reach 10 million in 2007. This number is expected to further skyrocket as the US population ages and risk factors such as obesity, smoking and sedentary lifestyle increase. In 2002, more than 927,000 Americans died from heart disease-related conditions, such as heart attack, high blood pressure, stroke and heart failure. Despite advances in cardiovascular medicine, congestive heart failure death rates are still on the rise (57, 106). Attempts to improve cardiac function in the late phases of heart failure continue to be ineffective (1), and many believe the solution lies in prevention of underlying heart disease (138). Increasing evidence suggests that the progression of many cardiovascular diseases including hypertension, atherosclerosis, congestive heart failure and diabetes-associated vascular complications are attributed to increases in cellular oxidative stress (94, 95, 112, 143). Animal and human studies support a role for reactive oxygen species (ROS) in the onset and progression of cardiovascular disease (153, 154) and, while it has been thought that antioxidant therapy delays the onset of heart failure (253, 285, 286), recent clinical trials have yielded mixed results (12, 155, 206, 254, 276).

Oxidative stress is thought to be a contributing factor to the progression of complications of many cardiovascular diseases. Oxidative stress is a general term used to

describe the steady state level of oxidative damage in a cell or tissue caused by reactive oxygen species (ROS). ROS have been associated with the progression of cardiovascular disease, insulin resistance,  $\beta$ -cell dysfunction, impaired glucose tolerance and diabetes mellitus (13, 34-36, 77, 161, 240). In fact, clinical studies confirm that the incidence of heart disease is much greater among diabetics and is the leading cause of death in this population (97). An increasing body of literature supports the hypothesis that oxidative stress is a common pathogenic mechanism in these disease states and may explain why they often appear together or consecutively (13, 34-36, 77, 161, 240).

Another approach to combat the deleterious effects of ROS generation in the progression of cardiovascular disease is to use the cell's inherent ability to increase the expression of various stress-related proteins to eliminate the oxidative stress. The induction of a cell's endogenous defense mechanisms is, at least in part, due to the activation of the *cis*-acting regulatory element appropriately termed the antioxidant response element (ARE). The ARE is located in the 5' region of many genes involved in detoxifying the cell as well as maintaining the cellular redox potential. The ARE is conserved between species and genes and is activated in response to a variety of drugs and antioxidants including heavy metals, flavonoids, heme complexes, phenolic antioxidants and xenobiotics (223). The ARE was first discovered as an element that activated phase II detoxifiers and drug metabolizing enzymes and was distinguished from another *cis*-acting element, the xenobiotic response element (XRE), because it was not associated with a receptor mediated activation, but rather an intracellular event (257).

In response to oxidative stress, a cluster of genes commonly known as antioxidants and phase II enzymes can be transcriptionally regulated through the

activation of the NF-E2 related factor 2 (Nrf2) transcription factor (209), a member of the Cap 'N Collar (CNC) family of bZIP proteins (223). Nrf2 activation begins with oxidative stress, which either directly or through a signaling cascade leads to the activation of Nrf2 causing it to dissociate from the inhibitor protein Kelch like-ECH-associated protein 1 (Keap1) (120). The disruption of the Keap1-Nrf2 complex is mediated by either the direct release of Keap1 from Nrf2 by reaction of the oxidant with cysteines on the Neh (binding) domain of the Keap1 molecule (133); or through the phosphorylation of Nrf2 by some unknown second messenger and phosphorylation cascade. Various signaling cascades have been shown to promote the dissociation of Nrf2, including the MAPK kinase cascades of ERK, JNK and p38 (3, 56, 268, 304-306, 315, 316); the PI3 kinase cascade (128, 130, 165, 175, 252) and the PKC cascade (53, 103, 111, 163).

Once Nrf2 is activated, it translocates to the nucleus and binds a small Maf protein forming a heterodimer that binds to the regulatory element appropriately termed the antioxidant response element (ARE) (113). The Nrf2 protein recognizes the conserved core sequence TGACnnnGC on the ARE, (209). Many genes are known to have an ARE element, including heme oxygenase-1 (HO1), NAD(P)H quinone oxidoreductase 1 (NQO1), glutathione reductase, glutathione peroxidase, glutathione S-transferase, superoxide dismutase 2, and catalase. These genes have been shown to be upregulated or have increased activity after oxidative stress in cardiac cells (28-30, 54, 83, 108, 199, 260, 302, 303), brain (125, 174-176, 264, 266), as well as in other tissues such as the lung (8, 47-49, 51, 187, 198, 232, 269, 291), liver (39), vascular endothelium (26) and heart (31, 217, 248).

Based on reports in the literature, Nrf2 appears to be a universal activator of antioxidant genes, however evidence directly linking Nrf2 activation to protection in cardiac cells against oxidative stress is lacking. Therefore, we hypothesize that in the cardiac cell, oxidative preconditioning occurs through the Nrf2/ARE pathway and constitutive activation of this Nrf2 pathway will leave the cardiac cell in an oxidative stress-resistant state. The specific aims of this study were to characterize the gene expression and translation of the ARE-containing genes HO1 and NQO1 in the H9c2 cardiac-like cell line after oxidative stress and determine the effect of oxidative preconditioning on cell survival. Furthermore, it was determined whether 1) activation of ARE-containing genes (HO1 and NQO1) in response to oxidative stress was mediated by NF-E2-related factor 2 (Nrf2); and 2) whether constitutively expressing ARE-containing genes by blocking transcription of Kelch-like-E2 associated protein (Keap1), the Nrf2 inhibitory protein, would mimic the effect of oxidative stress preconditioning.

These studies target an important issue relating alterations in cardiomyocyte redox potentials to the development of functional abnormalities in such diseases as diabetic cardiomyopathy and atherosclerosis. An understanding of the pathways involved in oxidative stress on the heart is an important step in the development of strategies to reduce the incidence of heart disease and increase the overall life expectancy and quality of life for cardiovascular disease patients.

## **LITERATURE REVIEW**

The antioxidant response element (ARE) was first discovered in the 1970's. The ARE is a *cis*-acting regulatory element located in the 5' region of many genes encoding detoxifying enzymes and antioxidants. Transactivation by the transcription factor Nrf2 results in increased gene expression of ARE-containing genes such as heme oxygenase 1 (HO1), NADPH:quinone oxidoreductase 1 (NQO1), glutathione reductase, glutathione peroxidase, glutathione S-transferase, superoxide dismutase 2, and catalase. Activation of the ARE by Nrf2 has recently been implicated as a protective mechanism in cardiovascular disease and has been shown to protect against oxidative stress in the brain after stroke and in neurological disorders such as Alzheimer's and Parkinson's disease. Due to its apparent role in protection against oxidative stressors in various organs, Nrf2 has earned the title of the multi-organ protector (166).

### **I. DISCOVERY OF THE ANTIOXIDANT RESPONSE ELEMENT**

Phase I and II enzymes were originally thought to be induced by the well-characterized aryl-hydrocarbon receptor (AhR) mechanism. The AhR activates enzyme transcription with the direct binding of a xenobiotic to the aryl-hydrocarbon receptor (AhR). The active AhR dimerizes with the AhR-nuclear translocator protein, then translocates into the nucleus, and binds to the xenobiotic response element (XRE), a

DNA enhancer sequence. Xenobiotics can activate phase I or phase II enzyme transcription separately or simultaneously, depending on their chemical properties (87, 88, 156, 195, 230). Phenolic antioxidants, for example, are capable of selectively activating phase II enzymes, whereas  $\beta$ -naphthoflavone is capable of activating both phase I and II enzymes (59, 127, 257). The AhR was thought to be responsible for the activation of both phase I and II enzymes, despite the ability of different compounds to selectively activate phase I and II enzyme transcription.

In 1985, a separate mechanism was proposed to be responsible for phase II enzyme induction based on the observation that azo dyes induce phase I and II enzymes differentially. It was suggested that phase I enzymes were induced by the previously-accepted AhR mechanism whereas phase II enzyme induction was thought to involve cytochrome P-450 ( $C^{P450}$ ). It was further suggested that metabolism of azo dyes by  $C^{P450}$  resulted in the generation of reactive species that were responsible for phase II enzyme activation (246). Similar observations were reported in other laboratories supporting a role for  $C^{P450}$  in mediating phase II enzyme activation. In one study, the administration of benzo[a]pyrene in cultured embryonic hamster cells resulted in the production of several redox-sensitive and toxic quinones. These compounds initially activated phase I enzymes, and only after an increase in  $C^{P450}$  activity did the levels of the phase II enzymes increase (156, 193, 230). As further support of  $C^{P450}$ -mediated phase II activation, the administration of SKF 525, a  $C^{P450}$  inhibitor, prevented the activation of phase II enzymes (107). Interestingly, a study by Denison found that the  $C^{P450}$  gene, *CYP1A1*, contains an XRE (60), suggesting that xenobiotics are able to increase their own metabolism by  $C^{P450}$  activating phase II enzymes. These data suggest that  $C^{P450}$  could be

involved in phase II enzyme induction by a different mechanism from that of phase I enzymes.

To determine whether the selective activation of phase II enzymes worked through the AhR pathway, cell lines expressing AhRs with low affinities for xenobiotics were generated. In these cells,  $\beta$ -naphthoflavone, a compound that activates both phase I and II enzymes, exhibited impaired phase II activation. However, the phenolic antioxidant *tert*-butyl hydroquinone was able to activate expression of phase II enzymes. These data suggested that phase II activation by phenolic antioxidants utilized a pathway separate from the AhR (257). Therefore, compounds that could induce both phase I and II enzymes through an AhR-dependent mechanism were termed bifunctional inducers, while those that regulate the expression of only phase II enzymes in a AhR-independent mechanism were termed monofunctional inducers (247).

In 1990, a novel *cis*-acting regulatory element was discovered in the 5'-flanking region of the glutathione S-Transferase Ya subunit that was responsive to the bifunctional inducer  $\beta$ -naphthoflavone ( $\beta$ -NF). To analyze the nature of this element, a reporter construct was generated containing the chloramphenicol acetyltransferase (CAT) gene fused with the cloned DNA element. Treatment with  $\beta$ -NF resulted in increased transactivation suggesting that the responsive element was activated by planar aromatic compounds like  $\beta$ -NF. Further analysis of the promoter element revealed distinct sequence differences from the xenobiotic response element (XRE). The new element was termed the  $\beta$ -naphthoflavone-response ( $\beta$ -NF) element (255, 283). The same element located in the promoter region of the rat glutathione S-transferase Ya A2 subunit gene was also identified by another group and was termed the electrophile response

element or EpRE (86). The two elements were later reclassified following data showing that phenolic antioxidants, like *tert*-butyl hydroquinone, increased transactivation of the DNA element through a C<sup>P450</sup> and the AhR independent pathway. The *cis*-acting DNA was renamed the antioxidant response element (ARE) (257).

## **II. XENOBIOTICS THAT ACTIVATE THE ANTIOXIDANT RESPONSE ELEMENT**

A structurally diverse group of compounds has been shown to activate transcription of antioxidant response element (ARE)-containing genes, including phenolic antioxidants, synthetic antioxidants (256), 3-hydroxycoumarin (139), isothiocyanates (22, 279, 280), GSH depleting agents (136), phorbol esters (111), flavonoids (256, 257) and 1,2-dithiole-3-thiones (157, 158) (table 1). These ARE-driven gene activators can be further subdivided into the monofunctional and bifunctional inducers. The monofunctional inducers, which activate gene expression through a mechanism separate from the AhR, have similar chemical properties in that they all react with sulfhydryl groups. The bifunctional inducers must be oxidatively metabolized by C<sup>P450</sup> prior to obtaining ARE-activating properties (69). For a complete list of ARE-inducing compounds, please see appendix A.

**Table 1:** Compounds that induce ARE-mediated transcription  
Modified from Nguyen *et al.*, 2003.

Class	Structure	Compound	Nature of compound
Synthetic phenolic antioxidant		Butylated hydroxyanisole (BHA)	Food preservative; Antioxidant in dermatological creams
Synthetic phenolic antioxidant		tert-butyl hydroquinone	Food preservative; Metabolite of BHA
Synthetic antioxidant		Ethoxyquin	Pesticide/insecticide; Pet food preservative
Synthetic antioxidant		Pyrrolidin-edithiocarbamate	Blocks NF-κB and activates iNOS
3-hydroxycoumarin		Coumarin	Chemopreventative agent in legumes
Isothiocyanate		Sulforaphane Oxidizes cysteines mimics oxidative stress	Chemopreventative agent in cruciferous vegetable
GSH depleting agent		Diethyl maleate Oxidizes cysteines mimicking oxidative stress	Synthetic compound inducing agent of drug metabolizing enzymes
Phorbol Ester		Phorbol 12-myristate (PMA)	Tumor promoting agent; PKC activator; Increases expression iNOS and COX-2
Flavonoid		β-naphthoflavone	Synthetic compound used as a model inducer of drug-metabolizing enzymes
1,2-dithiole-3-thione		Oltipraz	Cancer preventive agent Antischistosomal drug

### III. DISCOVERY OF Nrf2

As previously mentioned, the antioxidant response element was discovered by two separate groups simultaneously (257, 283). The EpRE and the  $\beta$ -naphthoflavone-response element *cis*-acting DNA elements were changed to the antioxidant response element (ARE) after it was reported to be responsive to phenolic antioxidants, namely *tert*-butyl hydroquinone (257). In 1991 the consensus sequence of the ARE 5'-TGACnnnGC-3', was discovered through the use of deletion mutants of the original

**Figure 1: Phase II enzyme induction distinct from the AhR pathway.**

The pathway states that bifunctional inducers activate the ARE through the generation of reactive oxygen species (ROS) from reactions with cytochrome p450. These ROS then react with a redox sensitive protein, later discovered to be Nrf2, and its interaction with the ARE results in the activation of transcription phase II enzymes. Modified from Nguyen *et al.*, 2003.

ARE/CAT reporter construct. In the same study, it was also reported that ARE/CAT transactivity was mediated directly through generation of reactive oxygen species (256).

The ARE was later reported to be in the promoter regions of the mouse glutathione S-

transferase Ya A1 subunit gene (86) and the rat and human NADPH:quinone oxidoreductase 1 genes (NQO1) (Figure 1) (78, 79, 184). This supports the theory that increased transactivation of the ARE is responsible for phase II enzyme induction.

The observation that reactive oxygen species resulted in the activation of this element gave rise to the hypothesis that a redox-sensitive transcription factor recognizes the DNA sequence of the ARE; furthermore, this protein-DNA interaction could be responsible for increased transcription of phase II enzymes (255).

The NF-E2 related factor 2 (Nrf2) protein was discovered while looking for proteins closely related to erythroid transcription factor NF-E2, a dimeric protein involved in the regulation of the globin gene in hematopoietic cells (6, 209, 219). Utilizing the Activator Protein 1 (AP1)-NF-E2 sequence as a probe to screen a cDNA expression library, two DNA binding proteins were discovered. One was identical to the recently discovered Nrf1 (NF-E2 related factor 1) and the second protein was named NF-E2 related factor 2 (Nrf2). Both Nrf1 and Nrf2 were also found to be ubiquitously expressed (38, 41). After the Nrf2 protein was cloned, several studies analyzed its sequence and predicted that it would have an activation domain, a cap'N'collar region (CNC), a DNA binding domain and a leucine zipper domain (37, 201, 209, 210) (Figure 2). The structural elements of the Nrf2 protein are present in other transcription factors that recognize AP1-like elements as well; therefore Nrf2 was proposed to recognize an AP1-like element.

## Nrf2

**Figure 2.** The structure of Nrf2. Nrf2 contains a hydrophilic N-terminus region followed by an acidic activation domain, a cap 'n' collar domain, a basic DNA binding domain and a leucine zipper. Figure modified from Moi *et al.* 1994.

The Nrf1 and Nrf2 proteins were identified in the context of studies aimed at identifying a redox-sensitive transcription factor that recognized the DNA sequence of the ARE. Nrf1 and Nrf2 have very similar tissue distribution to that of the ARE-driven gene, NADPH:quinone oxidoreductase 1 (NQO1) (293), and the similarity of the ARE and Nrf1/Nrf2 binding motifs implicated them as possible regulators of the ARE. To determine which protein was responsible for ARE-driven transcription, Venugopal *et al.* transfected HepG2 cells with Nrf1 or Nrf2 along with the ARE/CAT reporter construct. Cells transfected with Nrf1 and Nrf2, separately or combined, showed transactivation of the ARE/CAT reporter construct (293), implying both could be responsible for ARE-mediated gene transcription. Nrf1 and Nrf2 both recognized the ARE, increasing its transactivation and activating phase II enzyme transcription.

Both Nrf1 and Nrf2 were believed to be responsible for ARE-driven gene transcription until the Nrf2 knockout mouse was generated. This development led to the identification of Nrf2 as the major activator of ARE-driven gene transcription (41). Nrf2 was also shown to control the transcriptional activation of human  $\gamma$ -glutamyl cysteine synthase heavy and light subunits ( $\gamma$ -GCS<sub>h&l</sub>)(297), mouse heme oxygenase 1 (HO1) (2),

and rat NQO1 and GSTA2 subunits (220). Nrf2 was also shown to control both induced and basal levels of GSTA1 and NQO1 gene expression in Nrf2 knockout mice. Butylated hydroxyanisole (BHA), a phenolic antioxidant, was unable to stimulate ARE activity in the Nrf2 knockout mice (119), supporting the theory that phase II enzyme activation is dependent upon the Nrf2 protein. Further experiments using Nrf2 knockout mice also showed decreased NQO1, GST and  $\gamma$ -GCS enzyme activities (42, 201). For a complete list of Nrf2-regulated genes see appendix B. Following the development of the Nrf2 knockout mouse, ARE transactivation and phase II enzyme induction was attributed to the Nrf2 transcription factor.

#### IV. NRF2 ACTIVATION

**Figure 3.** Nrf2 activation The activation of Nrf2 can occur directly by oxidative stress or through a second messenger (MAPK, PI3 K or PKC) signaling the dissociation of Nrf2 (blue) from Keap1 (red). Upon separation, Nrf2 translocates into the nucleus and binds the ARE along with a co-transcription factor, thought to be small Maf protein (yellow). Upon binding Nrf2-Maf results in increased transcription of ARE-containing genes. Schematic is a modified version from Nguyen et al 2002 (223).

Transactivation of the antioxidant response element occurs when Nrf2 binds to the ARE. Nrf2 mediated activation was shown by transactivation of the ARE-CAT reporter construct and by studies using the Nrf2 knockout mouse. The proposed cascade for ARE activation (Figure 3) begins with a xenobiotic, which can activate Nrf2 directly through a redox reaction or indirectly through a signaling cascade (209). Nrf2 is present in an inactive form bound to Keap1 in the cytoplasm. Once activated, Nrf2 dissociates from Kelch like-ECH-associated protein 1 (Keap1) and translocates into the nucleus, where it binds to a co-transcription factor, the small Maf protein, forming a heterodimer. The Nrf2-Maf heterodimer recognizes and binds to the ARE and initiates the transcription of phase II enzymes.

Different signaling cascades have been reported to cause the dissociation of Nrf2, including the MAPK kinase cascades of ERK, JNK and p38 (3, 56, 268, 304-306, 315, 316); the PI3 kinase cascade (128, 130, 165, 175, 252) and the PKC cascade (53, 103, 111, 163). Current research indicates that the signaling cascade involved in the activation of Nrf2 is both gene- and tissue-specific.

**MAPK SIGNALING PATHWAY** The mitogen-activated protein kinase (MAPK) signaling pathway was the first investigated in Nrf2 activation. Extracellular signal regulated kinase 2 (ERK2) was shown to increase NQO1 transcription after tBHQ and sulforaphane treatment in mouse hepatoma cell lines. Using a dominant negative mutant of ERK2, ARE induction was blocked. These data suggest that ERK2 may be involved in signaling Nrf2 activation as well (305).

In contrast, the p38 MAPK pathway was shown to inactivate Nrf2. Treatment with tBHQ or  $\beta$ -naphthoflavone activated the p38 MAPK pathway in mouse hepatoma cell lines, but resulted in decreased Nrf2 activation. In addition, the p38 MAPK inhibitor SB 203580 and use of a dominant negative mutant of p38 resulted in Nrf2 activation and the increased transcription of NQO1. Thus, the activation of the p38 pathway resulted in a down-regulation of both basal and inducible ARE transactivation (306). The inhibitory role of p38 was later challenged when different findings resulted from treatment with the ARE inducer pyrrolidin-edithiocarbamate (PDTC) in human hepatoma cells. PDTC was reported to activate transcription of  $\gamma$ -glutamylcysteine synthetase heavy and light subunits ( $\gamma$ -GCS<sub>h&l</sub>) through p38 and ERK in a synergistic manner. Complete inhibition of transcription of GCS<sub>h&l</sub> subunit genes was obtained only when both pathways were inhibited by the use of the pharmacological inhibitors DP 98059 and SB 202190. In this study, p38 was implicated as an activator of ARE-driven transcription. Thus, p38 MAPK has been implicated as both a negative and positive regulator of ARE-driven genes. The different reports on the role of p38 can be explained in part by the use of different xenobiotics and different ARE-driven genes as an index of ARE transactivation. Thus the role of p38 is likely to be tissue-, gene-, and inducer-specific.

c-Jun N-terminal kinase (JNK), has also been implicated in Nrf2 activation. JNK was reported to activate Nrf2 after sodium arsenite and mercury chloride (304). This activation had a positive effect on NQO1 transcription, suggesting that JNK activates Nrf2- and ARE-driven transcription (304). These data support the JNK pathway as a possible mechanism in Nrf2 activation.

To date, the MAPK pathways have been reported to have both negative and positive effects on ARE transactivation. These studies have utilized different xenobiotics to activate the three major MAPK pathways and have yielded different results. Taken together, these studies show that the MAPK signaling pathway affects Nrf2 and ARE transactivation, but the role of p38 appears to be tissue-, gene-, and inducer-specific.

**PI3K SIGNALING PATHWAY** The phosphatidylinositol 3-kinase (PI3K) pathway has also been shown to be involved in Nrf2-ARE activation. Studies in the IMR-32 neuroblastoma cell line show that PI3K activates transactivation of a reporter construct containing the ARE from the NQO1 promoter. Using the pharmacological inhibitor of PI3K, LY 294002, there was an observed decrease in the transactivation of the ARE. In the same study it was also shown that ERK was not important for transactivation of the ARE. The pharmacological ERK inhibitor, PD 98059, had no effect on ARE transactivation (165), suggesting that ERK does not play a role in activating Nrf2 in neuroblastoma cells. Using microarray analysis, tBHQ was found to increase transcription of 63 genes in the IMR-32 cells. Of those, the transcription of 43 was blocked by LY 294002. The same group later showed that PI3K was involved in ARE-driven gene expression in primary cortical cultures derived from human placental alkaline phosphatase (hPAP) ARE reporter mice. Decreased hPAP activity was observed in cultures treated with LY 294002 (125, 152), supporting PI3K as an important second messenger in Nrf2 activation. These studies implicate PI3K as an important signaling pathway of ARE transactivation in neuronal cell lines and primary cultures.

**PKC SIGNALING PATHWAYS** In all of the studies elucidating the signaling pathway responsible for Nrf2 activation, PKC is the only second messenger shown to phosphorylate Nrf2 directly. Nrf2 is directly activated through phosphorylation by PKC at Ser<sup>40</sup> in the rat hepatoma cell line H4IIE (110, 111). To first evaluate the role of the PKC pathway in Nrf2 signaling, Huang *et al.* made reporter constructs containing the ARE from both NQO1 and GSTA2 promoter regions were generated. Decreased ARE transactivation was reported using broad spectrum PKC inhibitors (staurosporine and RO-32-0432) in response to tBHQ, TPA and  $\beta$ -naphthoflavone. Phosphorylation of Nrf2 was shown by radiolabeling experiments that indicated Nrf2 protein as being phosphorylated at Ser<sup>40</sup> by PKC. In addition, phosphorylation of Nrf2 by PKC resulted in Nrf2 translocation into the nucleus. To confirm these results, Ser<sup>40</sup> was mutated to an Ala and no detectable phosphorylation was observed compared to wild-type. Keap1 sequesters Nrf2 in the cytoplasm. Therefore the disruption of the Nrf2/Keap1 complex by phosphorylation was tested. Keap1 was labeled with <sup>35</sup>S, co-immunoprecipitated (coIP) with Nrf2, followed by SDS page, and free Nrf2 was determined by autoradiography. Thus, PKC phosphorylates Nrf2 at Ser<sup>40</sup> and causes both disruption of the Nrf2-Keap1 complex and Nrf2 translocation into the nucleus (110, 111). These experiments were the first to show a direct interaction by a signaling kinase and Nrf2, providing conclusive evidence that Nrf2 is activated by the second messenger PKC.

The signaling pathways of MAPK, PI3K and PKC have all been shown to be involved in Nrf2 signaling. It appears that MAPK signaling is important in hepatoma cell lines, whereas PI3K seems to regulate ARE-driven transcription in neuroblastoma cells and primary cortical astrocytes. The only signaling molecule shown to phosphorylate

Nrf2 directly is PKC, providing conclusive evidence that PKC acts as a regulator of Nrf2 activation. It is also possible that all three pathways are involved in Nrf2 activation and that the second messenger is dependent upon 1) the xenobiotic, 2) the gene measured and 3) the tissue or cell line used.

**NRF2 TRANSLOCATION** The import of Nrf2 into the nucleus is regulated by the nuclear localization signal (NLS), located in the C-terminus of the Nrf2 protein (122). Deletion of the NLS renders Nrf2 unable to enter the nucleus in response to the Nrf2 activating compound *tert*-butyl hydroquinone (tBHQ) (122). Once translocated into the nucleus, another mechanism prevents extended nuclear localization. The Nrf2 protein contains a redox-insensitive nuclear export signal (NES) (122, 182), which regulates its export from the nucleus. Deletion of the NES resulted in increased nuclear localization of Nrf2 after treatment with tBHQ (122). Nuclear export of Nrf2 occurs by the phosphorylation of tyrosine<sup>568</sup> on the Nrf2 molecule by the nuclear localized protein Fyn kinase, a member of the Src family. Crm1, a nuclear factor vital in deciphering nuclear export signals and exporting proteins from the nucleus (84, 229, 275), then recognizes the phosphorylated Nrf2, binds it and facilitates Nrf2 exportation (123). Together, the NLS and the NES tightly control nuclear localization of Nrf2.

## **V. DIFFERENTIAL REGULATION OF THE ARE**

The ARE is controlled by a number of factors that initiate or prevent ARE-driven transcription. The major positive regulator of the ARE is the Nrf2 protein, however NF-E2 related factor 1 (Nrf1) has also been shown to activate ARE-driven transcription.

Activating Transcription Factor 4 (ATF-4) and Nuclear Receptor-Associated Coactivator-3 (RAC3) have also been reported to increase ARE transactivation indirectly. Other proteins have been shown to negatively regulate the ARE including Keap1, Fos proteins, and Nrf3. All of these factors have been shown to bind the ARE, blocking the transcription of ARE-containing genes. The family of Maf proteins has also been shown to negatively and positively regulate the ARE depending on the dimer formed. A dimer consisting of two Maf proteins negatively regulates the ARE, whereas a heterodimer of Maf with Nrf2 results in activation. Maf, Fos and Jun all contain a DNA binding domain, but do not have a transactivation domain and, therefore, are unable to initiate transcription alone. The observation that multiple proteins can differentially regulate ARE activation suggests that they may play a role in the observed differential expression of ARE-containing genes.

**SEQUENCE OF THE ARE** Differential regulation of ARE containing genes can also be explained by the differences in ARE sequences. DNA footprinting and gel mobility shift assays have shown that the promoter regions differ between the rat GSTA2 and NQO1 genes, and these sequence differences are responsible for differential expression of GSTA2 and NQO1. In this study, exogenous Nrf2 coupled to the MafK co-transcription factor increased binding affinity for rat NQO1 when compared to GSTA2 (220). These data suggest that the gene-specific sequence of the ARE affects the binding of a specific Nrf2:Maf heterodimer.

**SMALL MAF PROTEIN** Binding of Nrf2 to the ARE requires the formation of a Nrf2 heterodimer with a co-transcription factor. The structurally similar NF-E2 protein heterodimerizes with a small Maf protein (113); suggesting that Nrf2 could also dimerize with a member of the Maf family (119). The small Maf family consists of three known members: MafF, MafG and MafK. Their structures consist of a DNA binding domain and a leucine zipper. They lack a transactivation domain making them function strictly as co-transcription factors (214). Within their DNA binding component, the small Maf proteins have a cap'N'collar (CNC) homology, facilitating the recognition of the AP1-like binding motif, as seen in the ARE (140). Small Maf proteins localize in the nucleus, binding to various transcription factors including Bach (231), NF-E2 (21, 113, 151, 197), AP1 (134) and Nrf2 (93, 197, 211, 220, 257, 297).

The small Maf proteins have also been shown to bind Nrf2 and to aid in the transcription of ARE-driven genes, although the isotype involved appears to be gene- and tissue- specific (197, 220). Studies have also shown a role for MafK (93, 211, 216, 220), MafG (211, 297) and MafF (211) in increased ARE transactivation. Transcription of the small Maf proteins can be induced by pyrrolidinedithiocarbamate (PDTC) and phenylethyl isothiocyanate (PEITC), but not tBHQ, suggesting that increased transcription of the small Maf protein is not necessary for ARE-driven transcription (211). The small Maf protein is vital for Nrf2 binding to its target (197, 220), because Nrf2 cannot form a homodimer to activate the ARE(209).

The small Maf proteins appear to act as molecular switches with respect to ARE gene transcription. In transfection studies using ARE/CAT fusion constructs generated from rat GSTA2 and NQO1 promoter regions, increased levels of MafK plasmid resulted

in decreased levels of transcription of Nrf2; and it appears that a concentration-dependent relationship between Nrf2 and MafK exists(65, 220). On the other hand, Nrf2 co-transfected at a 10-fold higher level than MafG resulted in an increase in transcription of  $\gamma$ -glutamylcysteine synthetase in both the heavy and light subunits. When the levels of MafG were increased, transcriptional inhibition was observed (297). The small Maf proteins have also been shown to form heterodimeric (134) and homodimeric transcriptional repressors (214) in response to increased ARE-driven transcription.

In all, the small Maf proteins act as transcriptional activators when bound to Nrf2, as well as a transcriptional inhibitors when bound to itself or other proteins. It has also been suggested that the small Maf proteins can act as either heterodimeric partners with transcription factors or as homo- or heterodimeric transcriptional repressors, as they lack the transactivation domain but still recognize the DNA sequence of the ARE (214).

**OTHER PROTEINS** Nrf2 has been reported to interact with other proteins, changing the transactivity of Nrf2. The cAMP Responsive Element Binding protein (CREB) binds to the Neh4 and Neh5 domains of Nrf2, increasing transcription of ARE-containing genes. This increase in ARE-driven gene synthesis is thought to occur due to the attraction of DNA polymerase by CREB (135). BTB and CNC homology 1 (Bach1) has been described as an negative regulator of Nrf2. Bach1 has also been reported to form a heterodimer with small Maf proteins, competing with Nrf2 for the ARE binding site(63). Nuclear receptor-associated coactivator-3 (RAC3) has been shown to activate ARE-driven transcription. RAC3 increased transactivation of Nrf2 when co-transfected with Nrf2 (186). Activating Transcription Factor 4 (ATF-4) has been reported to directly

increase HO1 transcription by dimerizing with Nrf2. A dominant negative mutant of the ATF-4 gene decreased Nrf2 transactivation, suggesting that ATF-4 is a positive regulator of Nrf2 and the HO1 gene (102). The Jun and Fos families of proteins have also been implicated as Nrf2 interacting proteins. The Fos family of proteins has repeatedly been reported as a negative regulator of the ARE (134, 140, 184, 191, 221, 293), whereas the Jun family of proteins has been shown to positively regulate the ARE (294). The interaction of other proteins with Nrf2 and the ARE effect the expression of ARE-driven genes in a gene-specific manner. These data suggest that other Nrf2 effector proteins differentially regulate ARE-driven genes and may be responsible for deciphering the intracellular signal as to which gene needs to be activated.

**NRF1** NF-E2 related factor 1 (Nrf1) was cloned in 1993 (37). It activates the ARE through direct binding and, when overexpressed alone or in conjunction with Nrf2, results in increased transactivity of the ARE (293, 294). Nrf1 is protective against oxidative stress in fibroblasts (160), lesioned hippocampus (104) and in liver cells against tert-butyl hydroperoxide-induced cell death (43). Unlike its family member Nrf2, Nrf1 gene disruption results in anemia and embryonic lethality in mice, suggesting that it plays a large role in development (38). Nrf1 has also been reported to crossover and interact with promoters other than the ARE. Nrf1, along with FosB, c-Jun, JunD and ATF2, has been reported to interact with the AP1 site of tumor necrosis factor  $\alpha$  (TNF $\alpha$ ), stimulating its transcription (224, 245). Nrf1 is negatively regulated through a different mechanism than that of Nrf2. Nrf1 is targeted to the endoplasmic reticulum (ER) membrane by its N-terminus, and upon endoplasmic reticulum stress, Nrf1 nuclear

localization is increased (296). These data suggest that while Nrf1 is able to modulate ARE-driven transcription, it may also play a role in ER stress.

**NRF3** Another member of the Nrf family, NF-E2 related factor 3 (Nrf3) was cloned in 1999. In this report, Nrf3 dimerization with MafK and binding of the heterodimer to the Maf recognition elements (MARE) within the  $\beta$ -globulin enhancer were observed (145). Nrf3 has been reported to negatively regulate the ARE when overexpressed in Hep-G2 cells through the formation of a heterodimer with a small Maf protein, competing with Nrf2 for the ARE. These results suggest that Nrf3 is a negative regulator of ARE-mediated gene transcription (259). A Nrf3 knockout mouse, generated in 2004, showed no apparent problems, even as a double mutant with the Nrf2 knockout. Nrf3 was found to be predominantly expressed in the placenta, B cells and monocytes (61). Upon closer analysis of Nrf3 in the placenta, it was determined that Nrf3 shows potent transactivation when forming a heterodimer with MafG on the NF-E2/Maf enhancer sequence. Nrf3 was present in placental chronic villi from 12 weeks of gestation until term and, interestingly, Nrf3 transcription and translation was reported to be activated by TNF  $\alpha$  (46). These data suggest that Nrf3 also plays a role in placental development.

A number of factors have been shown to influence ARE activation by Nrf2. The observed interaction of various proteins on Nrf2 and the ARE may explain the differential regulation of ARE-driven genes. Negative regulation is mediated not only by the Nrf2 inhibitory protein Keap1, but also by Nrf3 and the families of Maf and Fos proteins. Positive regulators include Nrf1, ATF-4, RAC3 and the families of Maf and Jun proteins. These studies suggest that differential regulation of ARE-driven synthesis

is due, at least in part, to the interactions of other regulatory proteins within the ARE system.

## **VI. DISCOVERY OF KEAP1**

In 1999, an inhibitory protein for Nrf2 was discovered (120). It was reported that the Neh2 hydrophilic domain of Nrf2 was not involved in transactivation. Upon deletion of the Neh2 domain and transfection of the mutant Nrf2 protein plus an ARE/LUC reporter construct, high levels of transactivation were discovered. It was concluded that this portion of the protein was somehow involved in negative regulation. In an effort to find an inhibitory protein, the Neh2 domain was used as bait in the yeast 2-hybrid system. Screening of 80 clones revealed that the majority encoded a single novel protein. Upon structural analysis of the novel protein, two characterized interaction domains (the BTB domain (14) and a double glycine repeat (DGR) domain (4)) were found. Bioinformatic database searches further revealed that the protein was very similar to the Drosophila cytoskeleton binding protein Kelch (298). The new protein was named Kelch-like associated protein-1 (Keap1) (120).

Keap1 was found to be expressed in a variety of mouse cell lines, with its highest expression in fibroblasts. Mutational analysis determined that the interaction between the Neh2 domain of Nrf2 and the DGR domain of Keap1 were responsible for Nrf2 inhibition. In the absence of the Neh2 domain of Nrf2, inhibition by Keap1 was lost. It was also reported that administration of electrophilic agents, namely diethylmalate (DEM) and catechol, caused the dissociation of the Nrf2-Keap1 complex, suggesting the interaction between Nrf2 and Keap1 was redox-sensitive (120). Given that Keap1 is

closely related to the cytoskeleton binding protein Kelch, it was hypothesized that Keap1 could also interact with the cytoskeleton, retaining Nrf2 in the cytoplasm. In QT6 cells transfected with fluorescently-tagged Keap1-green fluorescent protein (GFP), expression of Keap1 was localized in the cytoplasm. Cytoplasmic localization was confirmed in cells transfected with unlabelled Keap1 and fluorescently-labeled Neh2 domain of Nrf2 (120). Subsequently, it was shown that Keap1 binds to actin via the DGR domain, sequestering Nrf2 in the cytoplasm (131). Similar results were reported by Dhakshinamoorthy *et al.* (64). These studies showed that the newly discovered Keap1 protein is responsible for negative regulation of Nrf2 through binding of the DGR domain on Keap1 and the Neh domain on Nrf2. In addition, Keap1 negative regulation of Nrf2 was shown to occur by cytoplasmic retention through an interaction between Keap1 and actin filaments.

The cellular sensor within the Nrf2-Keap1 complex responsible for separation of Nrf2 from Keap1 was discovered in 2002 (68). It was proposed that there must be a cellular sensor within the Nrf2-Keap1 complex, either by alkylation or oxidation, that induces the dissociation of Nrf2. Nrf2 activation was shown in response to treatment with nine structurally-dissimilar classes of compounds, the only similarity being their ability to react with thiol groups. Due to the fact that Keap1 is cysteine rich and Nrf2 has relatively few cysteine residues, it was proposed that the thiol reaction occurs within the Keap1 protein. Through competition binding studies and kinetic measurements of the thiol reaction on Keap1 with dipyrindyl disulfides it was determined that there were four reactive cysteines. Confirmation of these results with radiometric, UV spectroscopic and mass spectrophotometric techniques showed four especially reactive cysteines, including

Cys<sup>257</sup>, Cys<sup>273</sup>, Cys<sup>288</sup> and Cys<sup>297</sup> on Keap1 (68). It was concluded that these cysteines were responsible for the dissociation of Nrf2 from Keap1 by a direct thiol reaction with the Nrf2 activating compounds. Conversely, it was reported that modification of these cysteines by a variety of known ARE inducers was insufficient to disrupt the Nrf2/Keap1 complex (72), although this study used lower concentrations of the ARE inducers. Overall, evidence supports the idea of reactive cysteines serving as redox sensors within the Keap1-Nrf2 complex which, upon reaction with an inducer, results in Nrf2 activation. This thiol reaction is dependent upon xenobiotic concentrations.

The first study to suggest that Nrf2 could be a substrate for proteosomal degradation reported that inhibition of the 26S subunit of the proteasome induced expression of the catalytic subunit of gamma-glutamylcysteine synthase, a Nrf2-regulated gene. This report was followed by a series of studies further implicating the proteosomal pathway in Nrf2 degradation showing that Nrf2 is an extremely labile protein and is rapidly identified and degraded by the proteosomal system (277). A month later it was reported that, upon activation, Nrf2 was stabilized and not degraded by the 26S proteasome (222). However, Nrf2 activation by antioxidants or overexpression resulted in increased expression of proteasome 20, suggesting that Nrf2 might increase proteasome levels as a negative feedback mechanism (159). It is thought that Nrf2 is constitutively ubiquitinated and degraded by the proteasome through the Nrf2:Keap1 interaction, and that Nrf2 is stabilized by oxidative stress through the antagonism of this interaction (202). These results suggest that proteosomal degradation of Nrf2 is dependent upon Keap1. The role of Keap1 as the regulator of Nrf2 translocation and degradation was later confirmed and found to be slowly degraded in the nucleus (121).

This interaction between the proteasome and Keap1 was reported to involve two cysteine residues on Keap1, Cys<sup>273</sup> and Cys<sup>288</sup>. It was also determined that these cysteines are required for Keap1-dependent ubiquitination of Nrf2 (308). These studies outlined the proteosomal degradation of Nrf2 by the proteasome. Proteosomal degradation of Nrf2 requires interaction with Keap1. Upon dissociation from Keap1, Nrf2 is stabilized and not targeted for degradation by the proteasome.

The role of cullin 3-ROC1 in mediating Nrf2 degradation was reported by two different groups the following year (67, 146). Both studies reported that Keap1 functions as an adaptor protein for the cullin 3-ROC1 complex acting as an E3 ligase in the ubiquitin-dependent proteosomal system. Ubiquitin conjugation requires the action of three enzymes: the ubiquitin-activating enzyme (E1), the ubiquitin conjugating enzyme (E2) and the ubiquitin ligase (E3). The E3 ligases both recognize the substrate protein and catalyze the isopeptide bond between the substrate and the ubiquitin. These studies showed that Keap1 interacts with the cullin 3-ROC1 E3 ligase facilitating the degradation of Nrf2 by ubiquitin-dependent proteosomal system (67, 146). A study by Kobayashi *et al.* (147) showed that the cullin 3-Roc E3 ligase complex requires Cys<sup>273</sup> and Cys<sup>288</sup> on Keap1 in order to ubiquitinate and subsequently degrade Nrf2. In the presence of an oxidant, Cys<sup>273</sup> and Cys<sup>288</sup> are oxidized and subsequently inactivate the cullin 3-ROC1 E3 ligase complex resulting in the release and stabilization of Nrf2 (147). This same group proposed a “fixed ends model” which suggests that a single Nrf2 protein is bound in two sites to two separate Keap1 monomers. The double-binding of Nrf2 to Keap1 facilitates an opening of the Neh domain of Nrf2 for the cullin-3-ROC1-E3 ligase complex to ubiquitinate Nrf2 and target it for degradation (Figure 5) (203, 287, 288).

These studies established the role of the proteasome in Nrf2 degradation, concluding that through two cysteines on the Keap1 molecule, the proteasome actively degrades Nrf2 and when the two cysteine residues are oxidized the proteasome is inactivated.

The Keap1 protein prevents Nrf2 activation by a direct binding to the Nrf2 protein and the actin skeleton. This interaction was reported to occur by the binding of the DGR domain of the Keap1 molecule to the Neh domain of the Nrf2 protein. The binding is redox sensitive, with four reactive cysteines on Keap1 that can react with known Nrf2 activators, resulting in the dissociation of Nrf2. Keap1 not only inactivates Nrf2, but also actively recruits Nrf2 for degradation by the proteosomal system. Each Keap1 molecule binds two Nrf2 proteins and facilitates their degradation by the cullin 3-ROC1 E3 ligase, a member of the proteasome. Taken together, These studies show that Keap1 is the major regulator of Nrf2 activation through direct binding action, as a redox sensor and recruitment of Nrf2 for proteosomal degradation.

### **VIII. Nrf2 as a multi-organ protector.**

The Nrf2/ARE system has been shown to be protective in many tissues and disease states. Nrf2-mediated protection is attributed to its unique ability to induce the transcription of phase II antioxidants and detoxifying proteins that neutralize reactive oxygen species and thereby balance the cells redox state. Since the discovery of Nrf2, its protective effects have been demonstrated in the lung, brain, endothelium, epithelium, kidney, pancreas and cardiovascular system and it has been shown to protect against many forms of cancer. The widespread reach of the protective effects of the Nrf2 protein has earned it the title of “the multi-organ protector” (166).

**NRF2 IN THE LUNG** Nrf2 protection in the lung was at first attributed to the proteins controlled therein. In 1996, a review article was published on the protective effects of the inducible protein heme oxygenase 1 (HO1). The authors concluded that HO1 induction was caused by a wide array of chemically diverse compounds and protects against oxidant-mediated lung injury, thus maintaining cellular homeostasis (51). The protective effects of ARE-containing genes, such as HO1, against oxidative stress was attributed to ARE-mediated transcription (58). Nrf2 has been found to protect the lung against a host of pulmonary diseases, including pulmonary fibrosis (50), hydroxytoulene-mediated pulmonary dysfunction (40), acute pulmonary injury (40, 198), asthma (180), hyperoxic lung injury (47, 234, 235) and emphysema (115, 117, 251). Somatic mutations within the Keap1 molecule have been implicated in the pathogenesis of lung cancer (68, 232, 269). Deletion, insertion and missense mutations of Keap1 have been detected in cancer cell lines as well as in samples from patients with non-small cell lung cancer at frequencies of 50% and 19%, respectively. These mutations appear to be localized in the DGR domain of the Keap1 molecule, decreasing or abolishing the affinity of Keap1 for Nrf2 (232, 269). While Nrf2 protects the lung against many pathologies, increased free Nrf2 caused by non-functional Keap1 has been implicated in the development of non-small cell lung cancer. Nrf2 in the lung has been extensively reviewed (48, 49, 291).

**NRF2 IN THE SKIN** A role for Nrf2 in skin biology was recently defined. The skin is constantly bombarded with UV radiation, inducing the formation of reactive oxygen species (ROS). Additionally, skin wounds attract inflammatory cells which release large

quantities of ROS. The first report that Nrf2 was present in skin was its induction by keratinocyte growth factor, a compound released in response to injury (24). Since then, a role for Nrf2 in wound healing has emerged. Increased levels of Nrf2 have been found in wounded tissues (20, 237) while Nrf2 has been reported to be activated by lipopolysaccharide (LPS) (242, 258, 274, 284). In addition, Nrf2 has been shown to be activated by the inflammatory molecule, 15-deoxy-delta (12,14)-prostaglandin J(2) (15dPGJ2), in epithelial cells (137). Nrf2 induction in keratinocytes has also been reported using various inducers and insults. First, treatment with Keap1 siRNAs results in an increase in ARE-containing gene expression (62). ARE-driven gene induction has been reported in response to electrophiles, tBHQ, hyperoxia, H<sub>2</sub>O<sub>2</sub>, glucose oxidase (70), arsenic (238), and low to moderate doses of UV radiation (132, 238). These studies, suggest that Nrf2 plays a large role in maintaining a redox balance in the skin through the regulation of wound healing and protection against daily attacks of reactive oxygen species on the skin (20).

The role of Nrf2 in the skin is further revealed by the phenotype of the Keap1 knockout mouse. The Keap1 knockout is a lethal mutation and Keap1 knockout mice die in the first three weeks after birth from food obstruction and ulceration caused by hyperkeratosis in the esophagus and stomach. Furthermore, the Keap1 knockout mouse also has hyperthickening of the epidermis. Upon closer analysis, increased expression of keratin 1 and 6 in the keratinocytes was found (213, 295), suggesting that keratin genes in epithelia are hypersensitive to Nrf2.

Nrf2 may also play a role in the prevention of skin cancer. Nrf2 knockout mice exhibit skin papillomas in response to carcinogens at an earlier age and at a higher

quantity than that of wild-type. Upon closer analysis of the Nrf2 knockout mouse papillomas, decreased levels of  $\gamma$ -GCS and NQO1 were observed. Interestingly, ARE reporter mice treated with the same carcinogen showed no detectable increase in ARE induction. This suggests that basal Nrf2-driven gene expression is responsible for the anti-tumorigenic properties of Nrf2 (10).

Nrf2 has been implicated as a regulator of the redox status of the wound and has been shown to be activated by electrophiles, tBHQ, hyperoxia, H<sub>2</sub>O<sub>2</sub>, glucose oxidase, arsenic and low to moderate doses of UV radiation. Nrf2 appears to play a role in skin biology, as it responds to keratinocyte growth factor. Excessive free Nrf2, as seen in the Keap1 knockout mouse, increases expression of keratins 1 and 6 and results in hyperkeratosis and hyperthickening of the epidermis. Mice deficient in Nrf2 also have decreased expression of ARE-driven genes, causing increased skin papillomas. In all, while Nrf2 is an important protective protein in skin biology, free Nrf2 levels must be regulated by Keap1 to prevent deleterious effects.

**NRF2 IN THE VASCULATURE** The significance of reactive oxygen species in the vasculature is very complicated in that they not only act as signaling molecules, but can also be harmful substances (282). In the endothelium, shear stress stimulates ARE-driven gene transcription through the generation of reactive oxygen species (126), whereas the type of blood flow (laminar vs. oscillatory) can also affect Nrf2 activation (45, 109). The activation of Nrf2 in response to shear stress in the endothelium is thought to be mediated by the activation of the inflammatory factors cyclooxygenase-2 (Cox-2) and 15-deoxy-Delta-(12,14)-prostaglandin J12 (109). Vasodilation is a mechanism to relieve shear

stress (76). The vasodilator effect of dopamine in kidney endothelial cells is also mediated by Nrf2 (17).

One of the major tools that the vascular system utilizes to combat atherosclerosis is nitric oxide (NO). The actions of NO in the vascular system include vasodilation, interactions with proteins involved in prevention of platelet aggregation, inhibition of leukocyte adhesion, DNA synthesis, mitogenesis and proliferation of vascular smooth muscle cells. NO has also been implicated in preventing thrombosis and plaque formation. The role of NO in the vasculature has been extensively reviewed (85, 281, 314)). Activation of Nrf2 by NO has been documented in both endothelial and smooth muscle cells, suggesting a possible role for Nrf2 in NO signaling. Nitric oxide (NO) has been reported to activate Nrf2 in endothelial cells, resulting in Nrf2 translocation and protection of the endothelial cell from oxidative injury and subarachnoid hemorrhage (44, 90). In smooth muscle, Nrf2 is also activated by NO and protects the cell from nitrosative stress (189). Studies have shown that activation of antioxidant genes by Nrf2 through NO (189, 217) and from the more harmful peroxynitrate ion (129, 178, 236) protects vascular smooth muscle against cell death. The reports of Nrf2 activation by NO in both layers of the vasculature suggests that it might be acting as a signaling molecule between the cellular layers of blood vessels. No evidence of a direct interaction between nitric oxide synthase (NOS) and Nrf2 has been reported. Therefore, Nrf2 is likely a downstream target of NO.

Other ROS in the vasculature have been reported to activate Nrf2. Nrf2 is both activated in response to, and is protective against H<sub>2</sub>O<sub>2</sub> in both smooth muscle (25) and endothelium (58). Oxidized lipids and lipoproteins have been shown to accumulate in

atherosclerotic lesions and contribute to the pathogenesis of atherosclerosis (18, 170, 278) while oxidized low density lipoproteins (LDL) activate Nrf2. These data implicate Nrf2 as a sensor of the redox state of oxidized lipoproteins (7, 172, 181). The activation of Nrf2 by oxidized lipids has been hypothesized to occur through nitric oxide production (270), leaving room to speculate as to the role of Nrf2 in the pathogenesis of atherosclerosis. Nrf2-mediated protection in the vasculature may be due to the unique ability of Nrf2 to act as a redox sensor in the vasculature. Nrf2 activation in the vasculature has been reported in response reactive oxygen species such as oxidized lipoproteins, H<sub>2</sub>O<sub>2</sub> and NO, but a correlation of Nrf2-mediated protection in the vasculature has not been made.

**NRF2 IN THE RETINA** The tubtub strain of mice are used as a model of adult onset obesity and is characterized by late-onset weight gain accompanied by progressive retinal and cochlear degeneration and tubtub mice (226, 227). Treatment of these mice with sulforaphane, a Nrf2 activator, increases antioxidant enzyme transcription through Nrf2, delaying the characteristic phenotype of photoreceptor degeneration (150). The role of Nrf2 in other aspects of the tubtub mouse phenotype has not been evaluated. However, Nrf2 may prove to play a role as oxidative stress has been shown to exacerbate many of the complications of obesity (13, 34-36, 77, 161, 240).

**NRF2 IN THE KIDNEY** In the kidney, ischemia-reperfusion often results in renal failure (263). Through microarray analysis after ischemia-reperfusion of the kidney, ARE-driven genes including glutathione S-transferases (GSTM5, GSTA2 and GSTP1),

and NAD(P)H quinone oxidoreductase (NQO1) were shown to be elevated. Nrf2 was also shown to be upregulated and, upon closer analysis, reoxygenation-specific nuclear accumulation was observed. These results suggest that Nrf2 might be involved in ischemic preconditioning through the activation of ARE-driven genes (171). Nrf2 has also been shown to be protective in other conditions of renal stress.  $\alpha$ -lipoic acid, a known Nrf2 activator, has been implicated in protection against hypertension and nephrotoxicity after treatment with cyclosporine, a drug used after organ transplants (194). These reports suggest Nrf2 is involved in renal protection against ischemia-reperfusion and hypertension-induced nephrotoxicity through the activation of ARE-driven genes.

**NRF2 IN THE LIVER** Primary hepatocytes and the HepG2 cell line are considered good models of intact liver (32, 148) and with these useful tools, Nrf2 activation has been implicated as a protective mechanism against many diseases of the liver. Treatment with antioxidants such as BHA and tBHQ, or oxidants like H<sub>2</sub>O<sub>2</sub>, results in increased phase II enzyme expression in both primary hepatocytes and the HepG2 cell line (5, 141). Using the HepG2 hepatic cell model, Nrf2 was shown to mediate protection against oxidative stress from arachidonic acid-induced toxicity (92). It has been also been suggested that Nrf2 protects hepatocytes from the deleterious effects of alcohol. Activation of cytochrome P450 2E1 (CYP2E1) and the ethanol-derived oxidative stress therein, is a well characterized harmful byproduct of alcohol metabolism (185). CYP2E1 activation was shown to be reduced by Nrf2 in human hepatocytes (91, 299). These data cast Nrf2 as a possible protective agent against cirrhosis of the liver. In addition to protection

against alcohol, treatment with sulforaphane, a Nrf2 activator, results in increased clearance of arsenic in mouse hepatocytes (267). In support of Nrf2 aiding in the clearance of toxic chemicals, the hepatocyte-specific deletion of Keap1 results in increased resistance in acute drug toxicity and increased expression of phase II enzymes (228). In summary, activation of Nrf2 by oxidants or antioxidants protects the hepatocyte from oxidative stress that could occur by poisoning, drug overdose or alcoholism. These data suggest that Nrf2 aids in the clearance of harmful chemicals by the liver and might have far-reaching implications for Nrf2 in the treatment of toxicity of the liver.

**NRF2 IN THE BRAIN** Research on the Nrf2/ARE pathway in the brain has been extensive and, for the most part, pioneered by Jeffery Johnson's group at the University of Wisconsin (167, 168, 173, 175, 208, 264). The ARE has been shown to be activated by tBHQ and phorbol -12-myristate-13-acetate in neuroblastoma cells (167, 175, 208). Pretreatment of tBHQ protects these cells from H<sub>2</sub>O<sub>2</sub> induced apoptosis (175). Nrf2 has also been shown to protect primary neurons against mitochondrial complex inhibitors (168, 264) and human neural stem cells against H<sub>2</sub>O<sub>2</sub>-mediated cell death (173). Nrf2 activation by oxidants and antioxidants protects neuronal cell lines and primary cultures from oxidative stress.

A role in astrocyte mediated protection of neurons has been extended to Nrf2. Nrf2 has been shown to protect astrocytes from H<sub>2</sub>O<sub>2</sub> (164) and, through the Nrf2/ARE pathway, astrocytes have been shown to protect neurons from H<sub>2</sub>O<sub>2</sub> and nonexcitotoxic glutamate toxicity (152). Glia overexpressing Nrf2 have also been shown to protect neurons against glutamate toxicity associated with glutathione depletion (265). These

reports suggest that Nrf2 is associated with the well-characterized protection of neurons by their neighbors (reviewed in (9, 15, 80, 144)).

Nrf2 activation has also been reported to protect the brain against severe stresses including cerebral ischemia (266, 311) and oligemia (191). Nrf2 may even have a role in protecting against Parkinson's disease (PD). Nrf2 knockout mice had increased susceptibility to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP; a model of PD) toxicity as compared to wild-type (27). In addition, pretreatment of human neuroblastoma SH-SY5Y cells with apomorphine resulted in increased cell survival against 6-hydroxydopamine (6-OHDA) toxicity through the activation of Nrf2 and transcription of ARE-driven genes (101). Nrf2-mediated transcription of ARE-driven genes appear to protect against treatment with MPTP and 6-OHDA, mimicking many pathologies of Parkinson's disease.

Nrf2 protects various constituents of the brain, including neurons, astrocytes and glia against various oxidative stressors. Nrf2 also protects the brain against cerebral ischemia, oligemia and may play a role in neuroprotection in Parkinson's disease.

**NRF2 IN CANCER** The pathogenesis of cancer is often caused by exposure to chemical insults. In response to these insults, the cellular defenses of antioxidant and detoxifying enzymes are coordinately activated by Nrf2 and aid in the clearance of these harmful substances. The use of the Nrf2 knockout mouse has been very useful in the study of the Nrf2/ARE system in cancer. Using the Nrf2 knockout mouse, chemotherapeutic agents have been shown to have decreased efficacy associated with decreased inducibility of antioxidant enzymes (116, 158, 250). Oltipraz, a

chemotherapeutic agent and Nrf2 activator, protects wild-type mice from the carcinogen benzo[a]pyrene, although increased tumor formation was observed in Nrf2 knockout mice (249, 250). Further, N-nitrosobutylamine caused increased lesion formation in the urinary tract and bladder of Nrf2 knockout mice compared to wild-type and treatment of wild type mice with oltipraz decreased lesion formation by 60-80% (114). Additionally, exposure to the well known carcinogens polycyclic aromatic hydrocarbons (PAH), derived from diesel exhaust, results in increased antioxidant enzyme levels in wild-type mice (179). The Nrf2 knockout mice, however, are more susceptible to DNA adduct formation in the lungs and increased inflammatory response in bronchial cells after treatment with PAHs (8). The selected studies outlined show a role for Nrf2 in cancer prevention through the increased expression of ARE enzymes. The role of the Nrf2/ARE pathway in cancer has been reviewed further (309).

**NRF2 IN THE HEART** While the role of Nrf2 in a cardiac setting has only recently been investigated, the protective nature of phase II antioxidants and detoxifying enzymes is well established (83, 108, 260, 303). Antioxidant enzymes protect against oxidative stress in many disease states, including myocardial infarction (105), hyperglycemia, (81) hypertension (54) and ischemia-reperfusion in both normal (261) and diabetic states (188). Furthermore, Nrf2 activators  $\alpha$ -lipoic acid (30), resveratrol (29) and 1,2-dithiole-3-thione (D3T) (28) activate transcription of antioxidant enzymes and protect the cardiac cell from oxidative stress. Although the protective effects of Nrf2 inducers and the antioxidant enzymes controlled therein have been shown to protect against various

cardiac diseases, a direct link between Nrf2 and the cardiac cell was not made until 2005 (313).

In 2005, Zhu *et al* (313) reported that Nrf2 protects Nrf2 knockout primary cardiac fibroblasts against reactive oxygen and reactive nitrogen species. The Nrf2 activator D3T was unable to protect Nrf2 knockout cardiac fibroblasts from oxidative and nitrosative stress as compared to wild-type. Additionally, the Nrf2 knockout mice had decreased activity and protein levels of superoxide dismutase (SOD), catalase, glutathione reductase (GR), glutathione peroxidase (GPx), glutathione transferase (GST) and NADPH:quinone oxidoreductase 1 (NQO1). In support of Nrf2-mediated protection in the cardiac fibroblast, xanthane oxidase and the NO-generating drug 3-morpholinosydnonimine-N-ethylcarbamide (SIN-1) caused increased cell death in Nrf2 knockout cardiac fibroblasts. It was concluded that Nrf2 is involved in inducible and basal induction of antioxidant genes and Nrf2 is protective against reactive oxygen and nitrogen species (313).

In 2007, Purdom-Dickinson *et al.* isolated cardiac myocytes and fibroblasts and using microarray analysis, produced an extensive list of enzymes with altered expression after treatment with H<sub>2</sub>O<sub>2</sub>. The list included antioxidant enzymes, metabolic enzymes, cytokines, endocrine factors, cell cycle regulatory proteins, cytoskeletal proteins, contractile proteins, and channel proteins (for a complete list see appendix B). They reported that, in cardiac myocytes, the ARE is activated in a dose- and time-dependent manner in response to H<sub>2</sub>O<sub>2</sub> using an ARE-luciferase reporter construct. Cardiac myocytes exhibited ARE binding and increased cell survival in response to doxycycline when preconditioned with H<sub>2</sub>O<sub>2</sub>. The investigators next examined if the preconditioning

effect seen by H<sub>2</sub>O<sub>2</sub> pretreatment was Nrf2 dependent. They determined that transient transfection of cardiomyocytes with Nrf2 was unable to protect against treatment with doxycycline. From this observation it was suggested that up-regulation of Nrf2 alone is not protective. The authors concluded that activation of the Nrf2/ARE pathway is not responsible for the preconditioning effect seen by H<sub>2</sub>O<sub>2</sub>, and further hypothesized that the interaction of Nrf2 with other pathways was responsible for the observed preconditioning effect of H<sub>2</sub>O<sub>2</sub> pretreatment.

The Nrf2 activators  $\alpha$ -lipoic acid, resveratrol, and 1,2-dithiole-3-thione (D3T) are reported to protect the cardiac cell from oxidative stress. Cardiac fibroblasts and myocytes derived from the Nrf2 knockout mouse have decreased ARE-driven enzyme levels and increased susceptibility to oxidative stress, suggesting that Nrf2 protects the cardiac cell from oxidative stress. On the contrary, Nrf2 overexpression does not protect against doxycycline-induced cell death, like that of H<sub>2</sub>O<sub>2</sub> pretreatment, suggesting that Nrf2 may not be involved in preconditioning the cardiac cell. It has been hypothesized that Nrf2 protects the cardiac cell through crosstalk with other protective pathways like NF- $\kappa$ B. It is unclear if the increased susceptibility to oxidative stress of Nrf2-deficient cardiac cells is due to direct actions of Nrf2 or a lack of crosstalk between Nrf2 and other pathways. The focus of the present study was therefore to determine if the transcription factor Nrf2 protects the cardiac-like H9c2 cell against oxidative stress.

In summary, Nrf2 activates phase II enzymes by recognition and direct binding to the ARE. Nrf2 activation can be attained through a direct reaction with an inducer or through a second messenger. MAPK, PI3K, and PKC have all been implicated in Nrf2 activation. Once activated, Nrf2 translocates into the nucleus where it binds to a co-

transcription factor, thought to be a small Maf protein, forming a heterodimer. The Nrf2:Maf heterodimer recognizes the ARE-initiating transcription of various antioxidants and detoxifying proteins. Nrf2 activation of ARE-driven genes is inducer-, gene- and tissue-specific and the differential regulation of ARE-driven transcription is thought to be mediated by both the sequence of the ARE and the Nrf2 co-transcription factor. Several negative regulators have been associated with the Nrf2/ARE system. Several proteins have been shown to form hetero- and homodimeric complexes occupying the ARE and preventing ARE-mediated transcription. The most important regulator of Nrf2, Keap1, binds directly to Nrf2, attaching it to the cytoskeleton and actively targeting it for proteosomal degradation (Figure 3). Nrf2 is ubiquitously expressed and reported to be protective in many tissues, earning it the title of the multi-organ protector. Protection by Nrf2 has been reported in tissues ranging from the skin and the lung, to the brain and the cardiovascular system. Taken together, the studies summarized here suggest that Nrf2 is protective in many disease states; overexpression and excessive Nrf2 activity can, however, be deleterious, thus ARE-driven transcription is heavily regulated.

## **MATERIALS**

H9c2 Cell line: Rat cardiac-like H9c2 cells were obtained from the American Type Culture Collection (ATCC, Manassas, VA) and used as the cardiac model system.

Cell culture supplies: Dulbecco's Modified Eagle's Medium (DMEM), fetal bovine serum (FBS), penicillin/streptomycin/amphotericin B reagent, Hanks Balanced Salt Solution with and without calcium and magnesium (HBSS), trypsin, and phosphate buffered saline (PBS) were purchased from Invitrogen Co. (Calsbad, CA). Culture dishes including T-75, T-25, 10 cm, 6 cm, 12 well, 6 well, 96 well, as well as cryotubes were purchased from B.D. Falcon Co. (Franklin Lakes, NJ). Conical Tubes (15 and 50ml) were purchased from Corning, Inc. (Corning, NY).

Nucleic acid and siRNA supplies: TRIzol, blue juice gel loading buffer, siRNAs for Nrf2, Keap1 and their corresponding nonsense control siRNA, lipofectamine and OptiMEM media were purchased from Invitrogen. RNeasy mini kit was purchased from Qiagen, Inc. (Valencia, CA). Taq polymerase and its corresponding 10X buffer were obtained from Eppendorf, Inc. (Westbury, NY). The IQ supermix for real time PCR, iScript first strand synthesis kit, and the 96-well optical plates and sealing tape were purchased from Bio-Rad Laboratories (Hercules, CA). Agarose, NorthernMax denaturing gel buffer, MOPS gel running buffer, formaldehyde sample loading dye, RNase and DNase-free water and DEPC-water were purchased from Ambion, Inc.

(Austin, TX). The all-purpose molecular weight ladder was purchased from Bionexus Inc. (Oakland, CA). Tris-Acetate-EDTA (TAE) buffer, Tris-EDTA (TE) buffer, chloroform were purchased from Fisher Scientific (Pittsburg, PA). Thin-walled PCR tubes, 1.5 ml, and 2 ml tubes were purchased from LabScientific (Livingston, NJ).

Western Blotting Supplies: DC protein assay kit, Laemmli buffer, Tris-glycine-SDS buffer,  $\beta$ -mercaptoethanol, pre-stained SDS-PAGE broad range molecular weight marker and 12% SDS-PAGE ready-gels came from Bio-Rad laboratories (Hercules, CA). ECL plus western blotting detection kit and nitrocellulose membranes were purchased from Amersham Biosciences (Buckinghamshire, England). Methanol was purchased from Fisher Scientific. Nonfat dry milk came from Nestle (Glendale, Ca). Rabbit anti-goat Nuclear factor E2 like 2 (Nrf2) primary antibody, rabbit IgG anti-heme oxygenase 1 (HO1) primary antibody and goat anti-rabbit HRP-conjugated secondary antibody were purchased from Stressgen (Victoria, Canada). Keap1 primary antibody, goat IgG anti-NADPH:quinone oxidoreductase 1 (NQO1) primary antibody and rabbit anti-goat HRP-conjugated secondary antibody were obtained from Santa Cruz Biotechnology (Santa Cruz, CA).

CyQUANT Cell Proliferation Kit and the Image-iT live green ROS detection kit were purchased from Molecular Probes/Invitrogen.

All other chemicals not mentioned were purchased from Sigma-Aldrich-Fluka (St. Louis, MO).

## METHODS

### **1 – Effect of tBHQ on HO1 and NQO1 gene expression of in the H9c2 cell line.**

#### **1.1 – Cell Culture:**

All cell culture techniques were performed under a sterile level 2 biosafety cabinet. The H9c2 cells were thawed rapidly in a 37°C water bath until 1/8<sup>th</sup> of the total volume remained frozen. Cells were then triturated gently into a 5 ml pipette containing low glucose (5.5 mM) DMEM supplemented with 10% fetal bovine serum, 100 mg/ml streptomycin, 100 U/ml penicillin F and 0.25 mg/ml amphotericin B (DMEM growth media). This cell mixture was then transferred to a 15 ml conical tube, brought up to a total volume of 10 ml in DMEM growth medium, and centrifuged for 5 minutes at 500 x g at room temperature. The supernatant was aspirated and the cell pellet was resuspended in DMEM growth medium. Cells were plated into a T75 flask and grown at 37°C in a cell culture incubator under 95% air and 5% CO<sub>2</sub>. Medium was changed after 24 hours.

After cell culture was established, medium was changed every three days and cells were passaged once per week at 90% confluence. For passage, cells were washed once with Hank's balanced salt solution (HBSS) without calcium and magnesium and trypsinized (0.05% trypsin w/v) for 5 minutes at 37°C. Cells were then gently rocked to remove any incompletely dislodged cells and 8 ml of DMEM growth medium was

added to the cells. Cells were then transferred to a 15 ml conical tube and centrifuged at 500 x g for 5 minutes at room temperature. Supernatant was removed and cells were resuspended in 10 ml of media and counted by trypan blue exclusion using a hemocytometer. Cells were plated at a density of  $2.5 \times 10^5$  cells/ 75 cm<sup>2</sup>.

The H9c2 cell line was derived from the left ventricles of neonatal rat hearts and can differentiate into either cardiac or skeletal muscle, depending on culture conditions (142, 205, 233). To ensure that our cells displayed the cardiac-like phenotype, mononucleation was verified by both 4',6-diamidino-2-phenylindole (DAPI) staining and hematoxylin-and-eosin (H&E) staining techniques.

**Figure 4:** H9c2 mono-nucleation verified by a) hematoxylin-and-eosin (H & E) stain (40x magnification) and b) 4',6-diamidino-2-phenylindole (DAPI) staining (20X magnification).

**1.2 – ARE-driven gene expression.** To determine the expression of Antioxidant Response Element (ARE) containing genes, tert-butyl hydroquinone was used to drive ARE gene expression. As discussed in the literature review, tBHQ is a phenolic antioxidant and well known activator of Nrf2 (activators summarized in table 1, page 9

and appendix A, page108 (223)). The optimum concentration of tBHQ was determined to be 10  $\mu$ M, with the greatest increase of HO1 and NQO1 gene expression at the lowest concentration of tBHQ. H9c2 cells were plated at a density of  $5.0 \times 10^5$  cells per 10 cm dish and grown to 80% confluence. Cells were treated with tBHQ (10  $\mu$ M) or its vehicle (1:20,000 dilution of DMSO) for 0, 4, 8, 12, 24, 36, 48 and 72 hours at 37°C in the cell culture incubator. At each time point, the medium was aspirated and 1 ml of TRIzol was added to each plate. Plates were mixed on a Belly Dancer (Stovall, Greensboro, NC) for 5 minutes, scraped into pre-labeled 1.5 ml tubes and stored at -80°C until use (see next section for details). This experiment was repeated in three independent experiments.

### **1.3 – RNA isolation from H9c2 cells:**

1.3.1 Phase Separation: The tBHQ or vehicle treated H9c2 cell samples in TRIzol were removed from the -80°C freezer and allowed to equilibrate to room temperature. Once equilibrated, 200  $\mu$ l of chloroform were added to each sample and samples were shaken vigorously for 15 seconds. The samples were allowed to sit at room temperature for three minutes, and centrifuged at 14,000 x g for 15 minutes at 4°C. Following centrifugation, the samples were separated into 3 distinct layers. The lower fraction is the organic phase and is red in color, the middle fraction, or interphase, is a white fluffy layer containing DNA, and the top clear aqueous phase contains the RNA. The top phase was carefully collected from the side, so as not to disturb the other phases. The extracted aqueous phase should be clear with no white fraction. The aqueous phase was transferred to a new, clean, pre-labeled 1.5 ml tube.

1.3.2 – Isolation of Total RNA Using the RNeasy Mini Kit: The aqueous phase obtained from the phase separation was combined with 350  $\mu$ l of 70% EtOH (v/v), vortexed, transferred into a spin column and placed into a 2 ml collection tube. Samples were centrifuged at 10,000 x g for 30 seconds at room temperature and flow through was discarded. Samples were washed with 700  $\mu$ l of RW1 buffer, centrifuged at 10,000 x g for 30 seconds and the flow through was discarded. To prevent contamination, the spin column was transferred to a new clean 2 ml collection tube, washed twice with 500  $\mu$ l of RPE buffer and centrifuged at 10,000 x g for 30 seconds at room temperature. The collection tube was discarded and replaced with a new pre-labeled 1.5 ml tube. RNA was eluted by pipetting 50  $\mu$ l of RNase- and DNase- free water directly onto the membrane of the silica gel column and incubating at room temperature for 5 minutes. The tube was centrifuged at 10,000 x g for 2 minutes and RNA in the flow through was either stored at -80°C or directly used in the next step.

1.3.3 – RNA Purity and Concentration Analysis: Sample RNA was analyzed spectrophotometrically for concentration and purity. The optical density of RNA samples was determined by UV spectroscopy using a SmartSpec plus spectrophotometer (Bio-Rad ). Sample RNA was diluted 1:100 in TE buffer (10 mM Tris-HCl, pH 7.5, 1 mM EDTA), transferred into a clean cuvette and analyzed spectrophotometrically using TE buffer as a blank. An absorbance at 260 nm of 1 is equivalent to 40  $\mu$ g/ml total RNA. Sample RNA concentrations ranged from 0.1 to 1.0  $\mu$ g/ $\mu$ l. Purity was also assessed by the ratio of absorbances from 260 nm and 280 nm ( $A_{260/280}$ ). If the  $A_{260/280}$  ratio was not greater than or equal to 1.7, the RNA purity was in question and samples were subjected to denaturing agarose gel electrophoresis to assess RNA integrity further.

1.3.4 – RNA Integrity Assessment: The purity and integrity of sample RNA was determined using denaturing-formaldehyde agarose gel electrophoresis (Mattheus *et al.* 2003). Total RNA (1 µg) was diluted in three volumes of formaldehyde sample loading dye (1X denaturing gel running buffer, 50% glycerol, 1mM EDTA, pH 8.0, 0.25% bromophenol blue, 0.25% xylene cyanol) and heated to 65°C for 15 minutes. Samples were then removed, condensed on ice, centrifuged at 1000 x g for 5 seconds and loaded on to the denaturing-formaldehyde agarose gel. A 1.2% (w/v) agarose gel was prepared in NorthernMax denaturing gel buffer per manufacturers instructions (1x MOPS, 50% formamide 6% formaldehyde; 1X MOPS buffer in DEPC water; 50% formamide, 6% formaldehyde). The gel was electrophoresed at 100 V for 30 minutes, removed from the chamber and stained for 15 minutes in 0.5 µg/ml of ethidium bromide in diethyl pyrocarbonate water (DEPC 0.1% w/v). The gel was destained in DEPC water for 1 hour, visualized via UV illumination, and an image was obtained using a FluorS multimager (Bio-Rad). The integrity of each RNA sample was determined by visual analysis of the 28S and 18S ribosomal RNA bands. Only samples where the 28S band were twice as dense as the 18S band (Figure 5) were used for further analysis.

**Figure 5:** RNA Integrity Gel. The quality of isolated RNA was assessed following formaldehyde-denaturing agarose gel electrophoresis. This image depicts a representative gel for control RNA sample isolated from H9c2 cells. Both ribosomal RNA 28s and 18s bands are clearly visible, with the 28S band twice as dense as the 18S band.

## **1.4 – Analysis of Gene Expression:**

1.4.1 – First Strand cDNA Synthesis: Total RNA was reverse transcribed to make cDNA using reverse transcriptase (RT). The cDNA was generated using the iScript first strand synthesis kit (4  $\mu$ l of 5X RT buffer, 1  $\mu$ l RT enzyme brought up to a total of 20  $\mu$ l with water) and 1  $\mu$ g of total RNA in a pre-labeled thin-walled PCR tube. The reaction was carried out on a Perkin Elmer model 2400 thermocycler under the following conditions: 25°C for 5 minutes followed by 42°C for 30 minutes then 85°C for 5 minutes with a final hold at 4°C.

1.4.2 – Real-Time PCR Primer Design: Primer design is crucial in reproducible and reliable gene expression analysis. Oligonucleotide primers were designed using vector NTI software (Invitrogen). General guidelines for primer design include a length of 18-24 base pairs, a GC content of 50-60%, a melting temperature ( $T_m$ ) between 50 and 65°C, no secondary structure, no repeats of G's or C's longer than 3 base pairs, no G's or C's at ends of primers, no 3' complementarity (also known as primer dimerization; set at  $\Delta G \geq -4$ ), a predicted amplicon size of 75-150 base pairs, and no secondary structure at binding sites. All criteria except the secondary structure can be programmed into the primer design tab of Vector NTI. Secondary structure of the gene and the amplicon were assessed using the mfold server provided by Dr. Michael Zuker (<http://bioinfo.math.rpi.edu/~mfold/dna/form1.cgi>). An 800 base pairs sequence of the gene to be amplified was analyzed for secondary structure under the following conditions: folding temperature 60°C, the ionic conditions of sodium (50 mM) and magnesium (3 mM). The derived secondary structure of the DNA was then used for

further primer design (Figure 6). Primers were designed in regions of no secondary structure. If an area of 150 base pairs without secondary structure was not found, the folding temperature was increased, keeping in mind that this then changed the temperature at which the primers were designed.

**Figure 6:** Mfold output. The secondary structure of the genes quantified by real-time PCR was assessed by the mfold server offered by Dr. M Zuker at Rensselaer Polytechnic Institute. This figure depicts the Nrf2 (Accession # NM\_031789) amplicon folded at 55°C with 5 mM Na<sup>+</sup> and 3 mM Mg<sup>2+</sup>.

The designed primer sequences were BLAST searched for gene specificity. BLAST is a search of all genes stored in the NCBI GenBank database and is available online at [www.ncbi.nih.gov/Genbank](http://www.ncbi.nih.gov/Genbank). If a match occurred for a gene other than the gene in which the primers were designed with an expectation number below 0.01, the primers

were discarded and new primers designed. The expectation number is the number of times this match would be expected to occur by chance in a search of the entire database. Two primer sets for each gene were designed and synthesized by Sigma-Genosys (St. Louis, MO).

Gene-specific primers designed for real-time PCR were: NAD(P)H quinone oxidoreductase 1 (NQO1), heme oxygenase-1 (HO1), NF-E2 related factor 2 (Nrf2), kelch-like associated protein 1 (Keap1) and the two housekeeping genes glyceraldehyde 3-phosphate dehydrogenase (GAPDH), and acidic ribosomal phosphoprotein Po (Arbp) (Table 2).

**Table 2.** Gene Specific Primers for Real-Time PCR

1.4.3 – Primer Specificity and Efficiency Verification: Before primers were used for real time PCR, each set was tested for specificity and efficiency. To make certain each primer pair had only one amplicon, a standard PCR reaction (2 µl cDNA, 5 µl reaction buffer, 1 µl dNTPs (0.2 M), 1 µl Taq (1.25 U) polymerase, 41 µl ddH<sub>2</sub>O) at the designated annealing temperature was performed (1 cycle 5 minutes @ 95°C; 40 cycles

15 seconds @ 95°C, then 30 seconds @ 60°C, then 15 seconds @ 72°C; and a final hold at 4°C) using control cDNA generated from the H9c2 cells. The PCR product was run on a 1.2% agarose gel, and the number and size of the band(s) were determined. Only primers with one amplicon of the correct size were used.

Primer PCR efficiency was determined by real-time PCR using a myIQ iCycler real-time PCR detection system (Bio-Rad ). A standard curve was generated using 10-fold dilutions of control cDNA and the newly designed primers (Figure 7). The reaction condition mixture consisted of 1.25 U platinum Taq polymerase, 20 mM Tris, pH 8.4, 3 mM MgCl<sub>2</sub>, 0.2 M each of the dNTPs, 50 mM KCl, 1:75,000 dilution of the DNA intercalating dye SYBR green (Platinum SYBR Green Supermix, Invitrogen), and the conditions were as follows: an initial denaturation at 94°C for 2 min, followed by 35 cycles of 94°C for 15 seconds, 60°C for 30 seconds and 68°C for 1 minute followed by a melt curve of 80 cycles starting at 55°C, increasing 0.5°C each cycle. The cycle threshold (Ct) was plotted against the cDNA dilution and the slope of the line was derived using the formula  $E = (10^{-1/\text{slope}}) - 1$ . E represents the efficiency of the reaction. Only primers with efficiencies of 80-120% were used for experimentation. In addition, the dilution series provided information regarding the correlation coefficient and only coefficients above 0.995 were used in these experiments.

Correlation Coefficient = 0.999  $Y = -3.227 + 12.223$

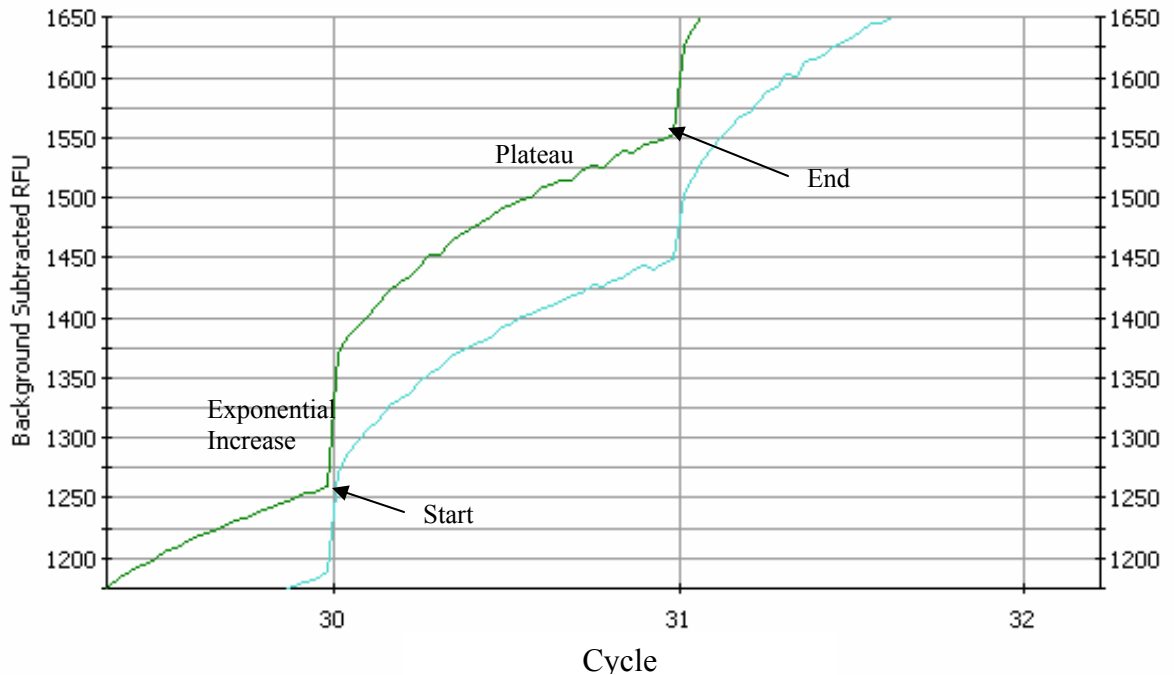

PCR Efficiency = 104.1

□ Unknowns  
 ● Standards

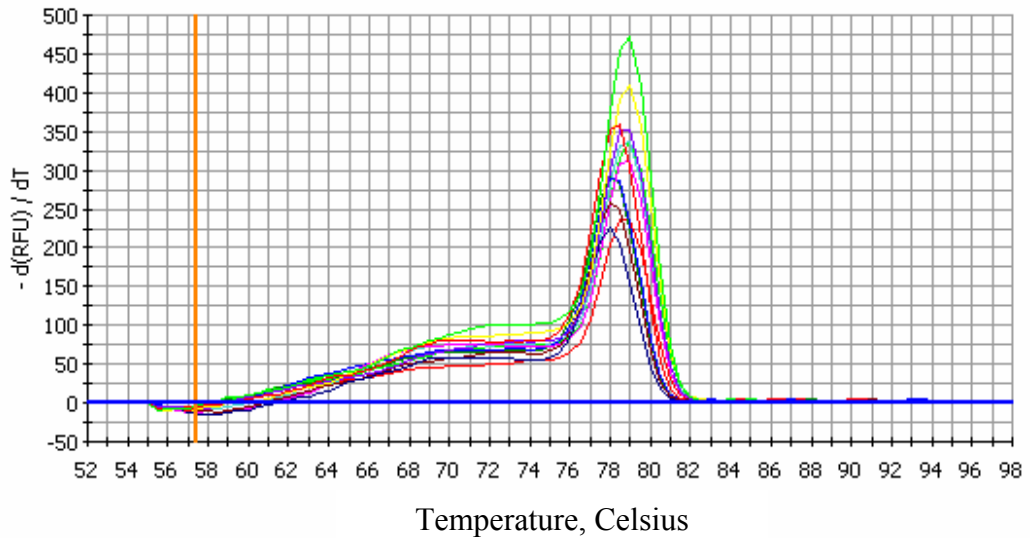

**Figure 7:** Real Time PCR standard curve for rat Nrf2 PCR efficiency. The primer efficiency was determined by a standard curve of serial dilutions of cDNA. The top graph is a representative real-time PCR quantification graph. The horizontal orange line is the cycle threshold (Ct), at which point the copies of the gene reach a threshold of fluorescence. Each curve represents a reaction with a certain dilution of cDNA in duplicate. The curves with the lowest Ct, represent the highest concentration of cDNA. The last 2 curves represent the blank (cDNA free) samples. The lower graph is a standard curve with cDNA concentration on the X axis and Ct on the Y axis. The PCR efficiency is 104.1% with a correlation coefficient of 0.999.

The data was further analyzed for efficient primer binding and for complete reaction elongation (Figure 8). To ensure efficiency of the primers, each curve should start above the previous curve and should increase exponentially at the start and plateau at the end. If these criteria were not met, the primers were discarded.

**Figure 8:** Primer binding and reaction elongation analysis. This graph represents a single cycle reaction of primer binding, elongation and primer unbinding of the gene heme oxygenase 1. Each trace represents a duplicate of a real-time PCR sample. Starting at cycle 30, an exponential increase in fluorescence is observed. This represents the primer binding to the template and the amplification of the target gene. The plateau phase represents the slowing and then end of the reaction when the next cycle begins with the 95°C segment.

To ensure that no 3' complementarity was present (primer dimerization), a melt curve was also performed (Figure 9). Each primer pair should have only one peak, indicative of one PCR product, and no secondary peak formation at 68-72°C (primer dimerization). If these criteria were not met, the primers were discarded.

**Figure 9:** Melt Curve analysis for primer dimerization. A melt curve of a representative Nrf2 amplification reaction. The single peak represents one amplicon with a distinct melting temperature  $T_m$ . The DNA synthesis is detected through dsDNA intercalation of the dye SYBR green. Little binding was present at 68-72°C, showing no primer dimerization.

1.4.4 – Primer Annealing Temperature: The last of the optimization experiments was an analysis of the annealing temperature. This consisted of running identical reactions using control cDNA at different temperatures and the temperature gradient function on the MyIQ real time unit. This tests annealing temperatures across a 20°C range, 10 degrees above and 10 below the designed annealing temperatures. As a rule of thumb, the temperature with the lowest Ct was chosen as the ideal temperature for the reaction to proceed.

1.4.5 – Real-Time PCR: Once primer and RNA quality was assessed, real-time PCR analysis of the ARE-containing genes was performed. H9c2 cells were treated with tBHQ and RNA isolated at time points of 0, 4, 8, 12, 24, 36, 48 and 72 hours. Expression of heme oxygenase 1 (HO1) and NADPH:quinone oxidoreductase 1 (NQO1) as well as the two housekeeping genes, glyceraldehyde 3-phosphate dehydrogenase

(GAPDH) and acidic ribosomal phosphoprotein Po (Arbp) were measured in duplicate on the myIQ iCycler real-time PCR detection system. No change was detected in housekeeping gene expression. The reaction mixture (conditions described in section 1.3.3) was as follows; 13  $\mu$ l SYBR green supermix, 10  $\mu$ l nuclease-free H<sub>2</sub>O, 1  $\mu$ l of 5  $\mu$ M primer mix (both sense and antisense suspended in 1X TE buffer) and 1  $\mu$ l experimental cDNA. The thermocycler program was as follows: an initial denaturation at 94°C for 2 minutes, followed by 35 cycles of 94°C for 15 seconds, 60°C for 30 seconds and 68°C for 1 minute. Each experiment was performed three to five times in duplicate and a cDNA-free sample (blank) was run with each primer to ensure contamination was not present.

1.4.6 – Real-Time PCR Analysis: Changes in gene expression of the ARE-containing genes HO1 and NQO1 were calculated relative to the gene expression at time zero. Matched-time vehicle-treated controls were checked prior to these experiments to verify no change in expression levels over time. The modified  $\Delta\Delta$ Ct method as described by Vandesompele *et. al* (292) was programmed into a Microsoft Excel macro (Bio-Rad ) and used for analyses of gene expression. This method was modified from the  $\Delta\Delta$ Ct method described in Livak and Schmittgen in 2001 (190) and uses complex algorithms that allow for use of multiple housekeeping genes.

## **2 – Effects of tBHQ on protein expression of HO1 and NQO1 in the H9c2 cell line.**

### **2.1 – Cell Culture:**

H9c2 cells were plated in 10 cm dishes and grown to 80% confluence as described in section 1.1. Cells were treated with 10  $\mu$ M tBHQ or its vehicle for 12 and 24 hours. Experiments were repeated four times in duplicate

### **2.2 – Preparation of Whole Cell Lysates:**

At each time point the medium was aspirated, dishes were placed on ice and 1 ml of ice-cold HBSS was added to each plate. Cells were scraped into pre-chilled 1.5 ml centrifuge tubes, centrifuged at 500 x g for 5 minutes at 4°C, the supernatant was aspirated, and cell pellets were resuspended in 100  $\mu$ l radioimmunoprecipitation (RIPA) lysis buffer (KH<sub>2</sub>PO<sub>4</sub> 10.6 mmoles/L, NaCl 1.5 moles/L, Na<sub>2</sub>HPO<sub>4</sub>·7H<sub>2</sub>O 29.7 mmoles/L, 1% Igepal, 0.5% sodium deoxycholate, 0.1% SDS, supplemented with 100  $\mu$ g/ml PMSF, 50 KIU/ml aprotinin and 100  $\mu$ l/ml of sodium orthovanadate), triturated through 100  $\mu$ l pipette tip and centrifuged at 10,000 x g at 4°C for 15 minutes. The pellet was discarded and the supernatant was stored at -20°C until further analysis.

### **2.3 – Determination of Protein Concentration:**

Protein concentration was determined using the DC protein assay (Bio-Rad), a colorimetric assay modified from *Bradford, 1976* (23). A standard curve was generated using BSA at concentrations ranging from 0.1 to 1.5  $\mu$ g/ $\mu$ l. The absorbance was measured at 750 nm on a SpectraMax Plus microplate reader (Molecular Devices Corp.,

Palo Alto, CA). Sample protein concentrations were determined based on the generated standard curve.

#### **2.4 – Western Blot:**

Cell lysate samples were standardized to 20 µg protein and boiled in equal volumes of Laemmli buffer (BioRad) containing 5% β-mercaptoethanol for 5 minutes. Samples were separated in a 12% total monomer polyacrylamide gel in the presence of sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis (SDS-PAGE). Following procedures for SDS-PAGE, the gel was then transferred electrophoretically to a nitrocellulose membrane. Membranes were blocked at room temperature in 5% non-fat dry milk in 1X TBS-T (20 mM Tris, 137 mM NaCl, pH 7.6; and 0.1% Tween 20) for 1 hour. Membranes were incubated with rabbit IgG anti-heme oxygenase 1 (HO1) primary antibody or goat IgG anti-NADPH:quinone oxidoreductase 1 (NQO1) primary antibody (1:3000 dilution) in 5% milk overnight at 4°C. Membranes were then washed three times for five minutes each with 1X TBS-T, and incubated in 5% milk containing either goat anti-rabbit IgG: horseradish peroxidase (HRP) conjugated secondary antibody or rabbit anti-goat conjugated IgG:HRP conjugated secondary antibody (1:5,000 dilution) at room temperature for 1 hour. Membranes were washed five times for five minutes each with 1X TBS-T, and immunoreactive bands were detected by chemiluminescence using the ECL Plus Western Blotting Detection System on a FluorS Multi Imaging System (BioRad). Densities of the resulting bands were quantified using Quantity One software (BioRad). Each western blot was performed twice to account for inter-assay variation.

### **3 – The effect of tBHQ on nuclear translocation of the transcription factor Nrf2.**

#### **3.1 – Cell culture:**

H9c2 cells were plated in 10 cm dishes and grown to 80% confluence as described in section 1.1, and treated with t-BHQ (10  $\mu$ M) or vehicle for 15 minutes.

#### **3.2 – Cytoplasmic and nuclear extractions:**

Cytoplasmic and nuclear extracts were isolated using the NE-PER Nuclear Extraction Kit (PIERCE Biotechnology, Rockford, IL). Cells were scraped into 1 ml of HBSS and centrifuged for 5 minutes at 1000 x g at room temperature. The cell pellet was then resuspended in 100  $\mu$ l of cytoplasmic extraction reagent (CER) I (proprietary recipe supplemented with 100  $\mu$ g/ml Phenylmethanesulfonyl fluoride (PMSF), 50 KIU/ml aprotinin and 100  $\mu$ l/ml of sodium orthovanadate), vortexed vigorously for 15 seconds and incubated on ice for 10 minutes. CERII buffer (5.5  $\mu$ l) was added, the sample was vortexed and the cytoplasmic fraction separated from the nuclear fraction by centrifugation at 15,000 x g for 5 minutes at 4°C. The supernatant (cytoplasm) was separated from the pellet (nucleus) and transferred to a pre-chilled tube. Nuclei were then lysed with the addition of 50  $\mu$ l of the Nuclear Extraction Reagent (NER; supplemented with 100  $\mu$ g/ml PMSF, 50 KIU/ml aprotinin and 100  $\mu$ l/ml of sodium orthovanadate), followed by four repeats of vortexing and incubation on ice for 10 minutes. Samples were centrifuged at 16,000 x g at 4°C for 10 min and the supernatant was stored at -80°C until use.

### **3.3 – Western Blot for Nrf2:**

Protein concentrations were determined as described in section 2.3. Western blot protocol was as described in section 2.4. Rabbit anti-goat Nuclear factor E2 like 2 (Nrf2) primary antibody was used at a 1:1000 dilution, and goat anti-rabbit IgG:HRP conjugated secondary antibody was used at 1:5000 dilution. Each sample was also probed with antibodies for  $\beta$ -tubulin to assess contamination from the cytoplasmic fraction into the nuclear fraction.

## **4 –Reactive oxygen species generation produced by the oxidant tert-butyl hydroperoxide.**

### **4.1 – Measurement of Intracellular ROS generation using microscopy:**

Intracellular reactive oxygen species (ROS) levels were determined using the Image-it Live Green ROS detection kit (Molecular Probes) (200). This protocol uses the fluorescent probe, 5-(and 6)-carboxy-2',7'-dichlorodihydrofluorescein diacetate (carboxy-H<sub>2</sub>DCFDA), a cell permeant dye that enters the cell and is cleaved by cellular esterases to the non-cell permeant non-fluorescent H<sub>2</sub>DCF. H<sub>2</sub>DCF is oxidized by ROS to the green fluorescent compound carboxy-DCF that can be detected by fluorescent microscopy.

H9c2 cells were plated on electrically charged cover slips (Fisher Scientific, Pittsburg, PA), and grown to 80% confluence. Cells were then treated in duplicate with tBHQ (10  $\mu$ M) or its vehicle for 24 hrs. After 24 hours, tert butyl hydroperoxide (tBHP, 100  $\mu$ M), an organic peroxide, or its vehicle was added for 2 hours. The cells were washed with 1 ml HBSS with calcium and magnesium and labeled with 25  $\mu$ M carboxy-

H<sub>2</sub>DCFDA in HBSS with calcium and magnesium for 30 min at 37°C in the dark. During the last five minutes, the nuclei were stained with the blue-fluorescent cell permeant nucleic acid stain Hoechst 33342 (1 µM). Cells were then washed five times with 1 ml HBSS with calcium and magnesium and coverslips mounted upside down on glass slides for ROS to be visualized in a double blind fashion using 40X magnification at Ex/Em 495/529 nm (green) and 350/461 (blue) on a Nikon 2000E fluorescence microscope. Images were merged and saved as JPEG files. Each experiments was repeated four times in duplicate.

#### **4.2 – Measurement of Intracellular ROS generation using a microplate reader:**

H9c2 cells were plated in 10 cm dishes and grown to 80% confluence as described in section 1.1. Cells were then treated in duplicate with tBHQ (10 µM) or its vehicle for 24 hrs. After 24 hours, tBHP (100 µM) or its vehicle was added for 2 hours. The cells were washed with 5 ml HBSS with calcium and magnesium, trypsinized and centrifuged at 500 x g for 5 minutes at room temperature. The supernatant was removed and cells were resuspended in 250 µl of carboxy-H<sub>2</sub>DCFDA (25 µM) in HBSS with calcium and magnesium for 30 minutes at 37°C in the dark. Each sample was washed once with 200 µl HBSS with calcium and magnesium, centrifuged at 500 x g for 5 minutes at room temperature, resuspended in 1 ml phenol red-free phosphate buffered saline (PBS) and counted (as described in section 1.1). Cells were added to black 96 well plates at a density of 50,000 cells per well in a volume of 200 µl. Plates were then read on a Fusion Universal microplate analyzer (Packard Instruments, Meriden, CT) at

excitation and emission wavelengths of 480 nm and 530 nm, respectively. Each experiment was repeated four times in duplicate.

## **5 – Effects of Nrf2 siRNA treatment on the protective effects of tBHQ.**

### **5.1 – RNA interference:**

RNA interference (RNAi) is a pathway in cellular defense against viral infection and transposons as well as functions as a method for post-transcriptional modification (100, 204, 262, 290, 307). It has recently been utilized as a unique form of post-translational gene silencing post-transcriptionally. The mechanism of RNAi starts with dsRNA that is recognized by the protein Dicer, which cleaves dsRNA into smaller (73, 169, 215) dsRNA fragments (19, 73, 74, 98). These fragments are then unwound and separated by the multi-protein RNA-Induced Silencing Complex (RISC) resulting in a single strand RNA-RISC complex (33, 99, 118, 225). The RNA-RISC complex binds to the target mRNA using the RNA as a probe and the RNA-RISC complex cleaves the mRNA in a site-specific manner. The cleaved products are then released and degraded, leaving the RNA-RISC complex to seek out more copies of the target mRNA and deplete the remaining pool of target mRNAs, resulting in gene knockdown (Figure 10) (73).

**Figure 10:** RNA interference. RNAi starts in the presence of dsRNA. dsRNA is recognized by the protein Dicer and cleaved into smaller (19-25nt) dsRNA fragments. These fragments are then unwound and separated by the multi-protein RNA-Induced Silencing Complex (RISC) resulting in a single strand RNA-RISC complex. This complex is then guided by the single strand of RNA to the target mRNA where it binds via complementarity and the mRNA undergoes site-specific cleavage.

A successful transfection of siRNAs is vital to investigating a biological role associated with gene silencing. For this reason, RNAi technology was validated using siTOX transfection control (Invitrogen). SiTOX is a cytotoxic, RNA-based reagent that is used to optimize transfection efficiencies. In addition, a positive control siRNA directed against the housekeeping gene glyceraldehyde 3-phosphate dehydrogenase

(GAPDH) was used to determine knockdown efficiency. To ensure that the siRNAs did not stimulate the antiviral interferon response, we measured the gene expression of a member of the antiviral response, 2'-5'-oligoadenylate synthetase (OAS2) (55), using real-time PCR in nonsense and siRNA transfected H9c2 cells.

### **5.2 – siRNA transfection efficiency:**

As mentioned on the previous page, transfection efficiency of the siRNAs was assessed by the siTOX transfection control (Dharmacon). Cells were grown to 25% confluence and treated with the proprietary siTOX RNA based cytotoxic agent. This agent results in cell death within 48 hours and correlates with transfection efficiency. H9c2 cells were plated at 50% confluence and treated with siTOX siRNA transfection control or nonsense siRNA. Cell survival after siTOX treatment was determined using the cell proliferation assay in duplicate (section 5.6.1) and transfection efficiency was found to be 42%. This experiment was repeated 3 times.

### **5.3 – Nrf2 siRNA treatment:**

H9c2 Cells were plated in antibiotic-free low glucose (5.5 mM) DMEM supplemented with 10% fetal bovine serum at a density of  $3 \times 10^5$  cells per 24 well plate. The cells were incubated overnight in normal growth conditions. The next day, cells were treated with 40 pmoles of all three non-overlapping Stealth<sup>TM</sup> (Invitrogen) siRNAs directed against rat Nrf2 (Accession number NM\_031789) or nonsense GC matched siRNAs (proprietary sequence) and delivered by Lipofectamine 2000 (Invitrogen) in OptiMEM medium (Invitrogen). Lipofectamine transfection reagent utilizes cationic

lipid-mediated transfection where siRNAs interact with the cell membrane in the form of a lipid:siRNA complex. This detergent-like structure is partially hydrophobic and hydrophilic, and enters the cell through endocytosis (11). The siRNAs (Table 3) were prepared in a 1:50 dilution of 20  $\mu$ M in OptiMEM (6 well plate: 10  $\mu$ l each siRNA into 500  $\mu$ l OptiMEM per well), and lipofectamine was prepared in a 1:100 dilution in OptiMEM medium (5  $\mu$ l lipofectamine per 500  $\mu$ l of OptiMEM per well) and incubated at room temperature for 5 minutes. Equal volumes of lipofectamine and siRNA mixtures (500  $\mu$ l of RNA mixture + 500  $\mu$ l of lipofectamine mixture per well of six well plate) were then combined and incubated for another 20 minutes at room temperature. The RNA/lipofectamine mixture was then added to the cells in addition to 1 ml of full growth medium (1 ml per well of six well plate) and incubated over night. Medium was changed 12 hours later to normal full growth medium containing antibiotic.

**Table 3:** siRNA sequences.

#### **5.4 – siRNA knockdown verification:**

After treatment with siRNAs, cells were incubated for a total of 64 hours and subsequently treated with tBHQ (10  $\mu$ M) or its vehicle for 8 hours. To verify gene knockdown, mRNA and protein levels for Nrf2 and Keap1 were measured and repeated in three independent experiments. Immunoblots for Nrf2 protein expression were performed as described in section 3.3 and repeated in three independent experiments. Nrf2 gene expression was determined using conventional (section 1.3.3) and real-time PCR (section 1.3.5) and repeated in three independent experiments. As mentioned previously, siRNAs mediated activation of the interferon (antiviral response) response was not detected using real-time PCR of 2'-5'-oligoadenylate synthetase (OAS2) (table 2) (55).

#### **5.5 –ROS generation in Nrf2 siRNA treated H9c2 cells in response to tBHP:**

To determine the effect of Nrf2 on ROS production in the H9c2 cell line, cells were treated as described above with Nrf2 siRNAs, incubated for 48 hours and subsequently treated with tBHQ (10  $\mu$ M) or its vehicle for 24 hours. Cells were then challenged with either 100  $\mu$ M tBHP or 200  $\mu$ M H<sub>2</sub>O<sub>2</sub> for 2 hours. Cells were trypsinised for 5 minutes, pelleted by centrifugation at 500 x g for 5 minutes at room temperature, and resuspended in HBSS containing carboxy-H<sub>2</sub>DCFDA (25  $\mu$ M) without Ca<sup>++</sup> and Mg<sup>++</sup>. Cells were incubated in the dark for 30 minutes at 37°C. Cells were then pelleted, washed in HBSS, counted using a hemocytometer (as described in section 1.1), and 50,000 cells were resuspended in 200  $\mu$ l of PBS without phenol red, plated per well of a black 96 well plate and read on a Fusion universal microplate analyzer at excitation

and emission wavelengths of 480 nm and 530 nm, respectively. Experiments were repeated three times and performed in duplicate.

### **5.6 – Effect of oxidative stress on H9c2 cell survival following Nrf2 knockdown:**

To determine the effect of Nrf2 on cell survival in response to H<sub>2</sub>O<sub>2</sub> and tBHP, cells were treated as described above with Nrf2 siRNAs, incubated for a total of 48 hours and subsequently treated with tBHQ (10 μM) or its vehicle for 24 hours. Cells were challenged with either tBHP (100 μM) or H<sub>2</sub>O<sub>2</sub> (200 μM) or their vehicle and incubated for 48 hours. Medium was aspirated and cells were immediately frozen and stored at -80°C. Control cells were counted, pelleted by centrifugation and stored at -80°C for the standard curve.

5.6.1 – Cell Proliferation Assay: The CyQUANT Cell Proliferation Assay Kit was used to estimate cell number. The kit utilizes CyQUANT GR, a green fluorescent dye, which fluoresces when bound to nucleic acids. Fluorescence from the DNA-bound dye is directly proportional to cell number and a standard curve was generated using control cells relating fluorescence to cell number. The standard curve is linear from 50 to 50,000 cells. A representative standard curve can be found in appendix D. Cell lysates from experimental samples and control cells for the standard curve were thawed to room temperature and resuspended in 500 μl lysis buffer containing the fluorescent dye CyQUANT GR (working lysis buffer). Control cells were also thawed and resuspended in the working lysis buffer. Samples were transferred in duplicate to a black 96-well plate (200 μl/well) and read on a Fusion Universal Microplate Analyzer at excitation and emission wavelengths of 480 nm and 530 nm.

## **6 – Effects of Keap1 siRNA treatment on the protective effects of tBHQ.**

### **6.1 – Keap1 siRNA treatment:**

H9c2 cells were plated in antibiotic-free low glucose (5.5 mM) DMEM supplemented with 10% fetal bovine serum at a density of  $3 \times 10^5$  cells per plate. The cells were incubated overnight in normal growth conditions. The next day, H9c2 cells were treated with 40 pmoles of three non-overlapping Stealth<sup>TM</sup> (Invitrogen) siRNAs directed against rat Keap1 (Accession number NM\_057152 ) or nonsense GC matched siRNAs and delivered by Lipofectamine 2000 (Invitrogen) in OptiMEM medium (Invitrogen) (Table 3). SiRNAs were prepared in a 1:50 dilution in OptiMEM (6 well plate: 10  $\mu$ l each siRNA into 500  $\mu$ l OptiMEM per well), and lipofectamine was prepared in a 1:100 dilution in OptiMEM medium (5  $\mu$ l lipofectamine per 500  $\mu$ l of OptiMEM per well) and incubated at room temperature for 5 minutes. Equal volumes of lipofectamine and siRNA mixtures (500  $\mu$ l of RNA mixture + 500  $\mu$ l of lipofectamine mixture per well of six well plate) were then combined and incubated for another 20 minutes at room temperature. The RNA/lipofectamine mixture was then added to the cells in addition to 1ml of full growth medium (1 ml per well of six well plate) and incubated over night. Medium was changed 12 hours later to normal full growth medium-containing antibiotic.

### **6.2– siRNA knockdown verification:**

After treatment with siRNAs, cells were incubated for 64 hours and subsequently treated with tBHQ (10  $\mu$ M) or its vehicle for 8 hours. In the absence of Keap1, tBHQ treatment should have little effect on ARE gene transcription, as Nrf2 would already be activated. To verify gene knockdown of Keap1, mRNA and protein levels were

measured. Immunoblots for Keap1 protein expression were performed as described in section 3.3 using primary Keap1 IgG (1:250 dilution) and secondary antibody rabbit anti-goat IgG:HRP (1:5000 dilution). Keap1 gene expression was determined using conventional (section 1.3.3) and real-time PCR (section 1.3.5). To ensure the siRNAs did not activate the interferon (antiviral) response, real-time PCR of 2'-5'-oligoadenylate synthetase (OAS2) was performed. Experiments were repeated three times and performed in duplicate.

### **6.3 – Effect of Oxidative Stress on cell survival following Keap1 Knockdown.**

After treatment with siRNAs for Keap1, H9c2 cells were then incubated for a total of 48 hours and subsequently treated with tBHQ (10  $\mu$ M) or its vehicle for 24 hours. Cells were then challenged with either tBHP (100  $\mu$ M) or H<sub>2</sub>O<sub>2</sub> (200  $\mu$ M) and incubated for an additional 48 hours. Medium was aspirated and cells were immediately frozen and stored at -80°C. Control cells were counted pelleted by centrifugation and stored at -80°C for the standard curve. Cell proliferation was assessed using the CyQUANT Cell Proliferation Assay Kit to quantify cell survival as described in section 5.5.1.

## **7 – The effect of Nrf2 overexpression in the H9c2 cell line.**

### **7.1 – Transfection of the H9c2 cells with Nrf2.**

The vector encoding Nrf2 tagged with green fluorescent protein (Nrf2-GFP) was a generous gift from Manabu Furukawa at the University of Nebraska, and was used in studies published by Furukawa *et al.* in 2005 (89). H9c2 cells were grown to 80% confluence and transfected with 0.5  $\mu$ g DNA containing Nrf2-GFP or empty vector

pcDNA 3.1 (p3.1), the same vector containing the Nrf2 construct. DNA was diluted in 500  $\mu$ M OptiMEM and lipofectamine was prepared in a 1:100 dilution in OptiMEM medium (5  $\mu$ l lipofectamine per 500  $\mu$ l of OptiMEM) and incubated at room temperature for 5 minutes. Equal volumes of lipofectamine and DNA mixtures were then combined and incubated for another 20 minutes at room temperature. The DNA/lipofectamine mixture was then added to the cells in addition to 1ml of full growth medium and incubated over night. Medium was changed 12 hours later to normal full growth medium containing antibiotic.

### **7.2 – Nrf2 overexpression verification.**

H9c2 cells were transfected with both Nrf2-GFP and p3.1 as described in section 7.1 and RNA was isolated 48 hours later as described in section 1.3. cDNA was generated and real-time PCR was performed using primers for HO1, NQO1 and Nrf2 as described in sections 1.4. Protein levels of Nrf2 were verified by western blot as described in section 3.3.

### **7.3 – Subcellular localization of Nrf2-GFP.**

Cells were plated and transfected as described in the previous section. Cells were then passaged and grown to 80% confluence on electrically charged cover slips (Fisher Scientific, Pittsburg, PA). Cells were treated with tBHQ (10  $\mu$ M) or vehicle for 1 hour and then coverslips were placed upside down onto glass slides. Cells were then visualized using a 40X magnification at Ex/Em 495/529 nm (green) and 350/461 nm (blue) on a Nikon 2000E fluorescence microscope. Images were saved as JPEG files.

#### **7.4 – The effect of Nrf2 overexpression on cell survival in response to H<sub>2</sub>O<sub>2</sub> and tBHP.**

H9c2 cells were transfected with both Nrf2-GFP and p3.1 as described in section 7.1 and passaged into 6 identical wells of a 24 well plate. The next day cells were treated with tBHQ (10 µM) for 24 hours. Cells were then challenged with H<sub>2</sub>O<sub>2</sub> (200 µM) and tBHP (100 µM) and grown for 48 hours. The cell medium was then removed and the cell culture plate was frozen at -80°C. Cell survival was assessed by the cell proliferation assay as described in section 5.6.1.

### **8 – Experimental Design**

**8.1 – Gene Expression.** H9c2 cells treated with tBHQ (10 µM) or vehicle and at each time point RNA was isolated. Sample quality was verified, quantified and reverse transcribed. Real-time PCR was performed on each sample in duplicate. Each experiment was repeated three times.

**8.2 – Protein Expression.** H9c2 cells were treated with vehicle and tBHQ (10 µM) for 12 and 24 hours. Sample protein content normalized and western Blot analysis was performed in duplicate. Each experiment was repeated four times.

**8.3 - Nuclear Translocation.** H9c2 cells were treated for 15 minutes with tBHQ (10 µM) and nuclear and cytoplasmic compartments separated by differential centrifugation.

Sample protein content was normalized and western Blot analysis was performed in duplicate. Each experiment was repeated three times.

**8.4 - ROS generation.** H9c2 cells were treated with vehicle, tBHP (100  $\mu$ M), tBHQ (10  $\mu$ M), tBHQ (10  $\mu$ M) + tBHP (10  $\mu$ M) in duplicate. ROS generation was measured using the green fluorescent dye carboxy-H2DCFDA and cell nuclei were marked by DAPI staining. Each experiment was repeated 4 times.

**8.5 – ROS generation of Nrf2 transfected cells.** H9c2 cells transfected with siRNAs directed against Nrf2 or GC matched siRNAs. Both sets of siRNA transfected cells were treated with vehicle, tBHP (100  $\mu$ M), tBHQ (10  $\mu$ M), tBHP (100  $\mu$ M) and ROS generation measured using the dye carboxy-H2DCFDA on the fluorescence plate reader. Each experiment was repeated three times.

**8.6 – Cell survival of Nrf2 transfected cells.** H9c2 cells transfected with nonsense or Nrf2 siRNAs. Both sets of siRNA transfected cells were treated with vehicle, H<sub>2</sub>O<sub>2</sub> (200  $\mu$ M), tBHP (100  $\mu$ M), tBHQ (10  $\mu$ M), tBHQ (10  $\mu$ M) + tBHP (100  $\mu$ M) and tBHQ (100  $\mu$ M) + H<sub>2</sub>O<sub>2</sub> (200  $\mu$ M) and cell survival was measured using cell proliferation assay. Each experiment was repeated six times.

**8.7 – Cell survival of Keap1 siRNA transfected cells.** H9c2 cells transfected with nonsense and Keap1 siRNAs. Following transfection cells were treated with vehicle, H<sub>2</sub>O<sub>2</sub> (200  $\mu$ M), tBHP (100  $\mu$ M), tBHQ (10  $\mu$ M), tBHQ (10  $\mu$ M) + tBHP (100  $\mu$ M) and

tBHQ (100  $\mu$ M) + H<sub>2</sub>O<sub>2</sub> (200  $\mu$ M) and cell survival was measured using cell proliferation assay. Each experiment was repeated three times.

**8.8 – Nuclear localization of Nrf2-GFP.** H9c2 cells were transfected with p3.1 or Nrf2-GFP. Following transfection cells were treated with tBHQ or vehicle for 12 hour. Cells were then visualized by fluorescence microscopy.

**8.9 – Cell survival of Nrf2 transfected cells.** H9c2 cells were transfected with p3.1 or Nrf2-GFP. Following transfection, cells were treated in duplicate with vehicle, H<sub>2</sub>O<sub>2</sub> (200  $\mu$ M), tBHP (100  $\mu$ M), tBHQ (10  $\mu$ M), tBHQ (10  $\mu$ M) + tBHP (100  $\mu$ M) and tBHQ (100  $\mu$ M) + H<sub>2</sub>O<sub>2</sub> (200  $\mu$ M). Cell survival was measured using cell proliferation assay and this experiment was repeated three times.

## **9 – Statistical Analysis**

All statistical procedures were conducted using Minitab (State College, PA). A paired t-test was used when samples were paired with a control. For example, the western blots for both HO1 and NQO1 were compared to time-specific vehicle-treated control. Differences between groups were assessed using a one-way ANOVA for multiple comparisons. Where differences were observed, a Tukey-Kramer *post-hoc* test was used. Statistical significance was set at  $p < 0.05$ . In real-time PCR experiments, significance cannot be assessed due to the constraints of the gene expression MACRO. Using this MACRO the expression of the control samples is automatically set to 1, preventing statistical analysis. However, the MACRO does assign a standard deviation to

the control samples and through comparisons of standard deviations one can assess significance.

## RESULTS

### **tBHQ- induced increase in HO1 and NQO1 gene expression:**

It has been reported that heme oxygenase 1 (HO1) and NADPH oxidoreductase 1 (NQO1) gene expression are regulated by the transcription factor Nrf2 after oxidative stress (3, 64, 124). Therefore we examined whether the expression of the antioxidant enzymes HO1 and NQO1 increased after treatment with the Nrf2 activator tBHQ (149, 165). H9c2 cells were treated with tert-butyl hydroquinone (tBHQ) (10  $\mu$ M) for 0, 4, 8, 12, 24 and 48 hours and RNA was isolated. Basal gene expression of HO1 and NQO1 did not change in vehicle-treated cells over a 48 hour period (data not shown). tBHQ (10  $\mu$ M) caused a significant ( $p > 0.05$ ) increase in both HO1 and NQO1 gene expression by 4 hours and each peaked at 8 hours (Figure 11). tBHQ caused a 7.6  $\pm$  0.5 fold and a 4.4  $\pm$  0.5 fold increase in expression at 8 hours compared to vehicle treated cells for HO1 and NQO1, respectively. By 48 hours, HO1 and NQO1 expression was not significantly different from the control. These data suggest that Nrf2 activation by tBHQ treatment resulted in increased transcription of the ARE-containing genes HO1 and NQO1.

**Figure 11.** Effect of tBHQ (10 $\mu$ M) on the expression of HO1 and NQO1. Cells were treated with tBHQ for up to 48 hrs and HO1 and NQO1 gene expression was measured by real time RT-PCR (n=3 independent experiments). Solid circle and line indicates HO1 gene expression. Open circle dotted line indicates NQO1 gene expression. Each time point is normalized to 2 housekeeping genes, glyceraldehyde 3-phosphate dehydrogenase (GAPDH) and acidic ribophosphoprotein (Abrp). Error bars represent standard error. \* Indicates significantly different from vehicle treatment at indicated time-point (p<0.05).

**tBHQ-induced increase in HO1 and NQO1 protein expression:**

To verify that HO1 and NQO1 protein levels increased after tBHQ treatment, HO1 and NQO1 immunoreactivity after tBHQ treatment was measured. Cells were treated with tBHQ (10  $\mu$ M) or vehicle for 12 and 24 hours, lysed and normalized for total protein. Basal levels of HO1 and NQO1 were detected in the lysate of vehicle treated cells. tBHQ significantly ( $p > 0.05$ ) increased the expression of HO1  $1.3 \pm 0.1$  fold after 12 hours and  $1.9 \pm 0.1$  fold after 24 hours relative to vehicle-treated cells (Figure 12.B), whereas the increase in NQO1 expression was only significant at 24 hrs. tBHQ increased NQO1 expression  $1.4 \pm 0.1$  fold after 12 hours and  $1.8 \pm 0.2$  fold after 24 hours relative to vehicle-treated cells (Figure 12.A). These data suggest that tBHQ increases HO1 and NQO1 translation.

**Figure 12.** Effect of tBHQ on protein levels of **A**) heme oxygenase-1 (HO1) and **B**) NAD(P)H:quinone oxidoreductase 1 (NQO1) immunoreactivity after 12 and 24 hour treatment (n=4 independent experiments). Protein levels were measured with specific antibodies for HO1 and NQO1 and data are expressed as fold increase compared to vehicle treatment for the same time point. Inlays are a representative western blot. Error bars represent standard error. \* Indicates significantly different from vehicle treatment at indicated time-point (p<0.05).

### **Nrf2 translocation into the nucleus after treatment with tBHQ:**

The transcription factor Nrf2 is sequestered and subsequently degraded in the cytoplasm in non-stressed cells (89). Upon activation, Nrf2 is released from Keap1 and translocates into the nucleus, increasing expression of ARE-driven genes. To determine whether treatment with tBHQ activates Nrf2 and causes its translocation from the cytoplasm to the nucleus, cells were treated with tBHQ and cytoplasmic and nuclear fractions were analyzed for Nrf2 immunoreactivity. Nrf2 immunoreactivity was detected in the cytoplasm at time zero of treatment and did not change after 15 minutes treatment with tBHQ. Nrf2 immunoreactivity was also detected at time zero in the nuclear fraction and its content increased significantly after treatment with tBHQ for 15 minutes.  $\beta$ -tubulin was used as a cytosolic marker and was detected in the cytosolic fraction but not the nuclear fraction. We also measured cytoplasmic and nuclear after tBHQ treatment for up to 8 hours. Nrf2 levels increased in both cytoplasmic and nuclear compartments in response to tBHQ treatment compared to time zero with, cytoplasmic Nrf2 levels remaining elevated 8 hours after tBHQ treatment. In the nuclear extract Nrf2 levels returned to basal levels by four hours of tBHQ treatment (Figure 13.C). These data suggest that tBHQ treatment activates Nrf2 and causes its translocation from the cytoplasm to the nucleus.

**A****B****C**

**Figure 13.** Effect of tBHQ on Nrf2 protein expression in **A**) cytoplasmic and **B**) nuclear compartments (n=4 independent experiments). Cells were treated for 15 minutes with tBHQ (10  $\mu$ M) and Nrf2 immunoreactivity was measured in the cytoplasmic and nuclear fractions. Protein levels were normalized and data are expressed as fold increase compared to vehicle treatment for the same time point. Inlays are a representative western blot. Error bars represent standard error.  $\beta$ -tubulin was used as a cytosolic marker. \* Indicates significantly different from 0 time point (p<0.05) **C**) Nrf2 levels after treatment with tBHQ (10  $\mu$ M) in the cytoplasmic and nuclear extracts (Representative figure of three independent experiments).

### **Nrf2 siRNA treatment attenuates HO1 and NQO1 expression:**

To determine the role of Nrf2 in mediating the expression of ARE-driven genes in response to tBHQ, a set of three Stealth<sup>TM</sup> RNAi directed against rat Nrf2 to knockdown Nrf2 were used. Treatment of H9c2 cells with the Nrf2 siRNAs for 12 hours decreased Nrf2 mRNA expression by 80% as compared to cells treated with nonsense (NS) siRNAs. In Nrf2 knockdown cells treated with tBHQ (10  $\mu$ M) for 12 hours there was also an 80% suppression of Nrf2 mRNA expression (Figure 14.A & B). Similarly, Nrf2 protein levels were also reduced following Nrf2 siRNA treatment for 12 hours (Figure 14.C).

Next whether Nrf2 siRNA treatment altered expression of the ARE-containing genes HO1 and NQO1 was examined. Basal gene expression of HO1 and NQO1 was decreased by 65% and 80%, respectively, in H9c2 cells treated with the Nrf2 siRNA compared to cells treated with nonsense siRNAs. In addition, tBHQ-induced induction of HO1 and NQO1 gene expression was reduced in Nrf2 siRNA treated cells. The increase in HO1 and NQO1 expression in response to tBHQ was reduced by 55% and 65% respectively, in Nrf2 knockdown cells as compared to nonsense siRNA treated cells (Figure 14.D) The increase in HO1 and NQO1 expression in response to tBHQ in nonsense siRNA treated cells was not different from that seen in control cells. These data suggest that Nrf2 knockdown attenuates the ARE-driven gene expression of HO1 and NQO1 in response to tBHQ treatment.

**Figure 14.** Effect of Nrf2 siRNA on Nrf2 gene and protein expression (n=3 independent experiments for each figure). **A)** Representative graph of RT-PCR of Nrf2 gene expression. **B)** Graphical representation of real-time RT-PCR of Nrf2 expression. The white bar represents a decrease in Nrf2 mRNA levels compared to nonsense siRNA treated basal conditions; whereas the black bar represents the decrease in Nrf2 levels as compared to nonsense (NS) siRNA treated with tBHQ. **C)** Representative western blot depicting protein expression of Nrf2 in whole cell lysates of nonsense (NS) siRNA and Nrf2 siRNA transfected cells. **D)** Effect of tBHQ (10  $\mu$ M) on HO1 and NQO1 gene expression in cells transfected with nonsense (NS) siRNA and Nrf2 siRNA after tBHQ treatment. Error bars represent standard error.

### **Activation of Nrf2 protects H9c2 cells against oxidative stress:**

To assess whether Nrf2 activation protects cells against subsequent oxidative stress, H9c2 cells were pretreated with tBHQ (10  $\mu$ M), challenged 24 hours later with tBHP (100 $\mu$ M) or its vehicle for two hours, and reactive oxygen species (ROS) generation was measured. ROS were measured using the Image-it Live Green ROS detection kit (Molecular Probes). This protocol was used for both the qualitative assessment of ROS generation using fluorescent microscopy and the quantitative measurement of fluorescent intensity. Cells were treated with vehicle, tBHQ, tBHP and a combination of pretreatment with tBHQ (10  $\mu$ M) then treatment with tBHP (100  $\mu$ M). In vehicle-treated cells, only blue nuclei were detected upon inspection with fluorescent microscopy. The nuclei appeared rounded with little to no visible green fluorescence (Figure 15.A.i). Treatment of cells for two hours with tBHP (100  $\mu$ M) caused the generation of green fluorescence throughout the cells indicative of ROS generation (Figure 15.A.ii). Pretreatment of H9c2 cells with tBHQ (10  $\mu$ M) had no effect on ROS generation, irrespective of whether it was measured at two hours (data not shown) or 24 hours after treatment (Figure 15.A.iii). However, the increase in ROS generation in response to tBHP was completely abrogated in H9c2 cells pretreated with tBHQ (10  $\mu$ M) for 24 hours (Figure 15.A.iv). Quantitative analysis of ROS generation measured by fluorescence intensity in suspended cells revealed similar results (Figure 15.B). tBHP (100  $\mu$ M for 2 hours) increased the fluorescent intensity significantly ( $p > 0.05$ ) compared to vehicle treated cells. Pretreatment with tBHQ (10  $\mu$ M) for 24 hours blocked this increase in ROS generation in response to tBHP (100  $\mu$ M). These data can be interpreted

to suggest that tBHQ, at a concentration demonstrated to activate Nrf2, is sufficient to decrease the cellular oxidative state even in the presence of the oxidant tBHP.

A

**Figure 15.** Reactive oxygen species generation. (n=4 independent experiments). A) ROS generation was visualized (40x magnification) using carboxy-H<sub>2</sub>DCFDA and the nuclei with the blue-fluorescent cell permeant nucleic acid stain Hoechst 33342. ROS generation is seen as green fluorescence and the nuclei are seen as blue. i-iv are representative fluorescence micrographs of four independent experiments. i) Vehicle treated. ii) 100  $\mu$ M tBHP for 2 hours iii) 10  $\mu$ M tBHQ for 24 hours iv) tBHQ (10  $\mu$ M) pretreatment for 24 hours, followed by 100  $\mu$ M tBHP for 2 hours. B) Quantitative measurement of ROS generation using fluorescence intensity in suspended cells. **Nrf2 knockdown increases tBHP-induced ROS generation:**

To further investigate the role of Nrf2 in protecting H9c2 cells against oxidative stress, cells were treated with Nrf2 siRNAs and ROS generation was measured in response to tBHP. tBHP (100  $\mu$ M for 2 hours) increased ROS generation in nonsense siRNA treated cells from  $1480 \pm 35$  in control to  $2109 \pm 37$  fluorescent units (FU). The tBHP-induced increase in ROS were enhanced in cells pretreated with Nrf2 siRNAs. In Nrf2 knockdown cells, tBHP approximately doubled the increase in fluorescence compared to nonsense siRNA treated cells. As described earlier in control cells (figure 15) tBHQ pretreatment also decreased tBHP-induced ROS generation in nonsense siRNA treated cells. However, this protective effect of tBHQ was lost in Nrf2 knockdown cells. ROS accumulation increased from control at  $1197 \pm 2$  FU to  $4268 \pm 438$  FU in Nrf2 knockdown cells pretreated with tBHQ (10  $\mu$ M) and then challenged with tBHP (100 $\mu$ M). Therefore, the inhibitory effect of tBHQ on tBHP-induced ROS accumulation was decreased in cells when Nrf2 was knocked-down by treatment with Nrf2 siRNAs (Figure 16).

**Figure 16.** Effect of Nrf2 siRNA treatment and tBHQ on intracellular ROS generation (representative graph of three independent experiments). Cells were treated with either the nonsense (NS) siRNA or the Nrf2 siRNA followed by pretreatment with tBHQ (10  $\mu$ M) or its vehicle for 24 hours. Cells were then exposed to 100  $\mu$ M tBHP for 2 hours, suspended, counted and ROS measured using carboxy- $H_2$ DCFDA. Error bars represent standard deviation within one experiment.

### **Nrf2 knockdown decreased cell survival after oxidative stress:**

Data from Figure 16 suggests that Nrf2 activation protects H9c2 cells against ROS accumulation in response to the prooxidant tBHP. To determine whether activation of Nrf2 can protect H9c2 cells from oxidant-induced cell death, cells were treated with Nrf2 or NS siRNAs and the effects of tBHP and H<sub>2</sub>O<sub>2</sub> on cell survival measured. In NS siRNA transfected cells, H<sub>2</sub>O<sub>2</sub> caused a  $72.8 \pm 4.1$  % decrease in cell number and tBHP caused a  $62.7 \pm 12.6$  % decrease in cell number. Pretreatment of NS siRNA transfected cells with tBHQ for 24 hours reduced the effect of tBHP to remote cell death. In Nrf2 siRNA transfected cells H<sub>2</sub>O<sub>2</sub> and tBHP caused a  $66.8 \pm 11.7$  % and  $72.8 \pm 9.7$  % decrease in cell number, respectively. tBHQ pretreatment had no effect on basal cell number but did not protect the cells from death in response to tBHP or H<sub>2</sub>O<sub>2</sub> as was seen in NS siRNA transfected cells. Therefore the ability of tBHQ to protect H9c2 cells from death in response to tBHP or H<sub>2</sub>O<sub>2</sub> was lost in Nrf2 knockdown cells.

**Figure 17.** Effects of Nrf2 knockdown on cell survival. H9c2 cells were transfected with either nonsense (NS siRNA) or Nrf2 siRNAs (n=6 independent experiments). Cell survival was measured by cell proliferation assay after the following treatments: vehicle (C), 200  $\mu$ M  $H_2O_2$  (2h), 100  $\mu$ M tBHP (2h), 10  $\mu$ M tBHQ (2h), 10  $\mu$ M tBHQ followed by 200  $\mu$ M  $H_2O_2$  (24h followed by 2 h respectively), and 10  $\mu$ M tBHQ followed by 100  $\mu$ M tBHP (24h followed by 2 h respectively). For the same conditions described above, bars and lines represent the mean and SE of for independent experiments performed in duplicate. \*Indicates significant difference from vehicle treated control (p<0.05).

**Keap1 knockdown increases HO1 and NQO1 expression:**

Keap1 is an inhibitory protein that sequesters and marks Nrf2 for proteosomal degradation. To determine if the protective effect of Nrf2 was enhanced by decreasing expression of Keap1 using siRNAs, H9c2 cells were treated with either nonsense (NS) or Keap1 siRNAs. H9c2 cells treated with Keap1 siRNAs had a tendency to be reduced as measured by real-time PCR and western blot (Figure 18.A&B). In Keap1 knocked down cells, basal HO1 and NQO1 gene expression increased  $2.6 \pm 0.5$  fold and  $4.6 \pm 0.6$  (SE) fold, respectively, as compared to NS siRNA transfected cells with fold change of 1. In addition, Nrf2 basal expression levels increased  $2.2 \pm 0.3$  fold. Pretreatment with tBHQ for 8 hours increased HO1 and NQO1 gene expression by  $9.3 \pm 0.5$  and  $8.32 \pm 3.8$  fold, respectively, in cells with Keap1 knockdown (Figure 18.C).

**Figure 18.** The effect of Keap1 siRNA on gene and protein expression. **A)** Real-time PCR of Keap1 mRNA levels after treatment with Keap1 siRNAs followed by treatment with 10  $\mu$ M tBHQ or vehicle for 8 hours as compared to nonsense (NS) siRNA treated control. **B)** Western blot of Keap1 protein levels after treatment with Keap1 siRNAs as normalized to nonsense (NS) siRNA treated control. **C)** Real-time PCR of HO1, NQO1 and Nrf2 mRNA levels after treatment with Keap1 siRNAs and after exposure to 10  $\mu$ M tBHQ or vehicle as compared to nonsense (NS) siRNA treated control. Error bars represent standard error.

### **Keap1 knockdown increases cell survival after oxidative stress:**

Under basal conditions, Keap1 knockdown increases HO1 and NQO1 gene expression (Figure 18). To determine whether Keap1 knockdown enhanced cell survival during oxidative stress, H9c2 cells were transfected with NS and Keap1 siRNAs, challenged with tBHP or H<sub>2</sub>O<sub>2</sub>, and cell survival was measured. In NS transfected cells, H<sub>2</sub>O<sub>2</sub> (200 μM) decreased cell number by 73.8 ± 3.0 %. Pretreatment with tBHQ 24 hours prior to exposure to H<sub>2</sub>O<sub>2</sub> inhibited the cell death by 27.3 ± 6.8 % in NS transfected cells. In contrast, cells transfected with Keap1 siRNAs H<sub>2</sub>O<sub>2</sub> did not cause a significant decrease in cell number both in the absence or present of tBHQ.

A similar trend was observed with tBHP (100 μM) treatment. In NS treated cells, tBHP reduced cell number to 49.14 ± 16.7 % as compared to control; whereas tBHQ treatment protected H9c2 cells from tBHP-mediated cell death (24.1 ± 15.0 %). In Keap1 knockdown cells, tBHP did not significantly decrease cell number (25.2 ± 12.2) and tBHQ pretreatment did not further increase cell survival (20.5 ± 13.3 %). These data suggest that Keap1 knockdown is sufficient to protect the H9c2 cells against oxidative stress caused by H<sub>2</sub>O<sub>2</sub> and tBHP. The protective effect of Keap1 is similar to that of NS siRNA treated control cells pretreated with tBHQ (Figure 19).

**Figure 19.** Effects of Keap1 knockdown on cell survival. H9c2 cells were transfected with either nonsense (NS siRNA) or Keap1 siRNAs (n=3 independent experiments). Cell survival was measured after the following treatments: vehicle (C), 200  $\mu$ M H<sub>2</sub>O<sub>2</sub> (2h), 100  $\mu$ M tBHP (2h), 10  $\mu$ M tBHQ (2h), 10  $\mu$ M tBHQ followed by 200  $\mu$ M H<sub>2</sub>O<sub>2</sub> (24h followed by 2 h respectively), and 10  $\mu$ M tBHQ followed by 100  $\mu$ M tBHP (24h followed by 2 h respectively). For the same conditions described above, bars and lines represent the mean and SE of for independent experiments performed in duplicate. \*Indicates significant difference from vehicle treated control (p<0.05).

**Nrf2 - GFP overexpression does not increase HO1 and NQO1 expression:**

Nrf2 has been shown to protect against oxidative stress, however Nrf2 overexpression has been reported to be unable to protect cardiac myocytes against doxorubicin toxicity (248). Therefore, it was next determined whether Nrf2 overexpression could activate ARE driven transcription and protect the H9c2 cells from oxidative stress. H9c2 cells were transiently transfected with human Nrf2 tagged with green fluorescent protein (Nrf2-GFP) or with empty pcDNA 3.1 vector. Nrf2-GFP was a generous gift from Dr. Furukawa at the University of Nebraska (89). Nrf2-GFP transfection increased basal human Nrf2 mRNA levels as compared to empty vector transfected control (Figure 20.A). H9c2 cells transfected with Nrf2-GFP had an increase in Nrf2 immunoreactivity, however there was no difference in HO1 and NQO1 mRNA expression as compared to empty vector transfected cells (Figure 20.C). tBHQ (10  $\mu$ M 24 hours) increased Ho1 and NQO1 gene expression similarly in both empty vector and Nrf2-GFP transfected cells (Figure 20).

**Figure 20.** Effect of Nrf2 overexpression on gene and protein expression. H9c2 cells were transfected with either Nrf2 tagged with green fluorescent protein (Nrf2-GFP) or empty pcDNA 3.1 vector (p3.1). **A**) RT-PCR of gene expression in empty vector and Nrf2-GFP transfected cells after treatment with tBHQ (10  $\mu$ M) or its vehicle for 24 hours (n=2 independent experiments). **B**) Protein expression of Nrf2 in empty vector (p3.1) and Nrf2-GFP transfected cells (n=3 independent experiments). **C**) Real-time PCR on the effect of tBHQ (10  $\mu$ M for 8hrs) on HO1 and NQO1 gene expression in cells transfected with Nrf2-GFP or empty vector (p3.1) (n=3 independent experiments). Error bars represent standard error.

### **H9c2 cells overexpressing Nrf2 - GFP require tBHQ for nuclear translocation:**

In an effort to investigate why Nrf2 overexpression did not increase transcription of ARE-driven genes, H9c2 cells were transfected with human Nrf2 tagged with green fluorescent protein (Nrf2-GFP) or empty pcDNA 3.1 vector and plated on charged coverslips. Cells were treated with tBHQ (10  $\mu$ M) or its vehicle for 1 hour and visualized via fluorescent microscopy. Background fluorescence was detected in the H9c2 cells transfected with empty vector and treated with vehicle (Figure 21.i). In H9c2 cells transfected with Nrf2-GFP, fluorescence was detected and appeared to be localized throughout the cytoplasm (Figure 21.ii). H9c2 cells transfected with empty vector and treated with tBHQ showed no significant fluorescence (Figure 21.iii), whereas H9c2 cells transfected with Nrf2-GFP and treated with tBHQ displayed localization of fluorescence in the nucleus (Figure 21.iv). These data suggest that overexpressed Nrf2-GFP remains predominantly in the cytoplasm until activated by tBHQ, at which point it translocates into the nucleus.

**Figure 21.** Cellular localization of Nrf2 tagged with green fluorescent protein (Nrf2-GFP) (40x magnification). H9c2 cells were transfected with either Nrf2-GFP or empty pcDNA 3.1 vector. **i.** Fluorescence of H9c2 cells transfected with pcDNA 3.1 empty vector and treated with vehicle for 1 hour. **ii.** Fluorescence of H9c2 cells transfected with Nrf2-GFP and treated with vehicle for 1 hour. **iii.** Fluorescence of H9c2 cells transfected with pcDNA 3.1 empty vector and treated with 10  $\mu$ M tBHQ for 1 hour. **iv.** Fluorescence of H9c2 cells transfected with Nrf2-GFP and treated with 10  $\mu$ M tBHQ for 1 hour. Representative figure of four independent experiments.

### **Nrf2 overexpression is not protective:**

To address whether Nrf2 overexpression protects H9c2 cells against lethal levels of oxidative stress, cells were transfected with Nrf2-GFP or pcDNA 3.1, challenged with H<sub>2</sub>O<sub>2</sub> or tBHP and cell survival was measured (Figure 22). In empty vector transfected cells, H<sub>2</sub>O<sub>2</sub> treatment increased cell death  $59.0 \pm 6.6$  % and tBHP treatment increased cell death to  $77.4 \pm 6.4$  % as compared to control. A similar trend was observed in cells overexpressing Nrf2. H<sub>2</sub>O<sub>2</sub> treatment increased cell death  $56.7 \pm 7.11$  % and tBHP treatment increased cell death  $67.4 \pm 10.7$  %. tBHQ treatment protected both Nrf2 overexpressing and empty vector control. In empty vector transfected cells, tBHQ treatment decreased cell death  $16.3 \pm 16.4$  % in H<sub>2</sub>O<sub>2</sub> treated and  $31.4 \pm 5.7$  % in tBHP treated cells. In Nrf2 overexpressing cells, tBHQ treatment decreased cell death  $10.7 \pm 7.0$  % after H<sub>2</sub>O<sub>2</sub> treatment and  $13.3 \pm 8.1$  % after tBHP treatment. While Nrf2 activation protected against oxidative stress and cell death, Nrf2 overexpression alone did not.

## DISCUSSION

These studies evaluated the protective nature of Nrf2 against oxidative stress in the H9c2 cardiac-like cell line. We used the antioxidant *tert*-butyl hydroquinone (tBHQ) to activate Nrf2. tBHQ treatment resulted in nuclear accumulation of Nrf2 and increased transcription of the ARE-driven genes, HO1 and NQO1. tBHQ treatment also protected H9c2 cells from reactive oxygen species (ROS) generation and prooxidant-induced cell death. The protective effects of tBHQ were mediated through Nrf2, as Nrf2 knockdown prevented transcription of HO1 and NQO1. Nrf2 knockdown increased ROS generation in response to the prooxidant *tert*-butyl hydroperoxide (tBHP) and increased cell death in response to H<sub>2</sub>O<sub>2</sub> and tBHP. In cells with reduced Nrf2 levels, tBHQ did not protect against ROS or cell death.

Knockdown of the inhibitory protein Keap1 increased expression of HO1, NQO1, and Nrf2. Keap1 knockdown was protective against prooxidant mediated cell death which was not further augmented by tBHQ treatment. Overexpression of Nrf2 did not cause increased transcription of HO1 and NQO1. This is likely due to nuclear exclusion of Nrf2. Only after tBHQ treatment did cells overexpressing Nrf2 exhibit increased enzyme transcription and nuclear localization. Thus Nrf2 appears to protect the cardiac-like H9c2 cells from oxidative stress when activated by Nrf2 or by the removal of Keap1. Nuclear exclusion of Nrf2 prevents increased gene transcription by Nrf2 overexpression unless Nrf2 is activated by tBHQ.

The rat cardiac-like H9c2 cells were used as the model cell system for this study. The H9c2 cells were developed in 1976 from the lower half of the embryonic rat heart consisting of mostly ventricular tissue (142). The H9c2 cell is a mononucleated spindle shaped large myoblast. At low densities, H9c2 cells retain their cardiac like phenotype which includes mononucleation, the ability to generate an overshooting action potential when stimulated, and a pattern of creatine phosphokinase CPK isoenzyme expression consistent with cardiac tissues. H9c2 cells also contain sarcomeres in the same pattern, diameter and structure of cardiac tissue. The H9c2 cell line can be used to represent both cardiac-like and skeletal muscle-like cells depending on growth conditions. To promote a cardiac-like phenotype, H9c2 cells were grown in the presence of 10% FBS and cultures were passaged every three days. These cells must reach confluence and grow for a period of three weeks before attaining the skeletal muscle phenotype (142). The mononucleated cardiac phenotype of H9c2 cells was verified periodically by both DAPI staining and hematoxylin-and-eosin (H&E) staining (Figure 4). To ensure that the H9c2 cells did not differentiate during the course of experimentation, only cells within the first 10 passages were used and gene expression analysis of HO1, NQO1, GAPDH and ABRP were measured to verify that the gene expression profile of H9c2 cell cultures remained consistent.

In the present study, we used the well known Nrf2 activator tBHQ to activate Nrf2. tBHQ caused an increase in mRNA expression of the genes HO1 and NQO1. tBHQ has been shown to activate Nrf2-mediated transcription using ARE-luciferase reporter constructs (149) and in ARE-hPAP reporter transgenic mice (125). In these studies, tBHQ activated Nrf2 resulting in ARE binding and transcription of ARE

responsive genes. In addition, a host of genes has been reported to be transcribed by Nrf2 after treatment with tBHQ including  $\gamma$ -glutamyl transpeptidase,  $\gamma$  glutamylcysteine synthase (187) HO1 (141), NQO1 (149) and many more, as determined by microarray analysis (173, 176).

The expression of protective enzymes has been shown to be controlled by Nrf2 in many tissues and cell lines, thereby supporting the hypothesis that Nrf2 is a multi-organ protector (166). In this study we found increased expression of the classical ARE-driven genes HO1 and NQO1 in cardiac H9c2 cells, consistent with the idea that the observed protective effect is a result of the activation of Nrf2.

Heme oxygenase-1 (HO1), the inducible form of the HO proteins, is activated in response to a host of oxidant and antioxidant stimuli (51). By degrading the reactive free heme into the antioxidants bilirubin and the anti-inflammatory agent CO, HO1 has been reported to protect cells against oxidative stress (52, 301, 302). HO1 has been shown to protect the heart in a variety of situations including after transplantation and against atherosclerotic lesion formation, while the lack of HO1 has been reported to exacerbate cardiac lesion formation after ischemia-reperfusion in normal and diabetic rats (188, 273, 300-302). Furthermore, HO1 transcription has been shown to be activated by the antioxidant response element (2). These studies, taken together, emphasize the importance of ARE-mediated HO1 expression in a cardiac system and make it an ideal reporter gene to analyze ARE activation.

NAD(P)H:quinone oxidoreductase 1 (NQO1) is an enzyme that catalyzes a two electron reduction of both exogenous and endogenous quinones, and quinone containing compounds including the tumor drug mitomycin C, vitamins K and E, and benzene

quinones (218, 223, 244). A lack of NQO1 or reduction of its activity has been linked to a number of cancers including leukemia and myelogenous hyperplasia as well as being associated with increased benzene hematotoxicity and a decreased response to chemotherapy. Thus, NQO1 has the beneficial effect of chemoprotection (16, 82, 162, 192, 212, 271, 272). NQO1 is constitutively expressed in most mammalian tissues and its induction requires the Nrf2-ARE pathway, making it a very useful reporter gene for studying the Nrf2-ARE system (196).

In the present study we did not investigate direct protective effects of HO1 or NQO1 induction. Instead, expression of HO1 and NQO1 was used as an index of ARE activation by Nrf2. HO1 and NQO1 are ideal reporter genes of ARE activation because they have sequence differences within the ARE and are differentially expressed in response to tBHQ treatment (Figure 13). Many other genes have been reported to contain AREs and to protect the cardiac cell after oxidative stress including glutathione reductase, glutathione peroxidase, glutathione S-transferase, superoxide dismutase, and catalase (28-30, 54, 83, 108, 199, 260, 302, 303).

RNA interference (RNAi) has recently been utilized as a unique form of post-transcriptional gene silencing. (100, 204, 262, 290, 307). siRNA technology works on the basis of creating RNA duplexes. The double-stranded RNA is recognized by the cells multi-protein RNA-Induced Silencing Complex (RISC) and degraded (for more information see section 5.1 of the methods section).

RNAi has several limitations. The cellular antiviral response is the most adverse side effect of siRNA technology. The antiviral response is characterized by the production of cytotoxic interferons and inflammatory cytokines. To overcome this

limitation we measured gene expression of a member of the interferon response cascade, 2'-5'-oligoadenylate synthetase (OAS2). We detected no change from control, suggesting that our siRNA transfection protocol does not activate the antiviral interferon response. In addition, lipid-mediated transfection is inherently toxic to the cell and can result in off-target or non-specific effects of the transfection. The nonsense siRNA control was used in parallel to the experimental siRNA in every experiment to ensure that observed effects were due to gene knockdown and not to nonspecific effects of the transfection.

Another limitation of RNAi is that gene expression is not completely eliminated and the effectiveness of different siRNAs varies. A positive control siRNA directed against the housekeeping gene glyceraldehyde 3-phosphate dehydrogenase (GAPDH) was used to determine knockdown efficiency. Using siRNAs generated against GAPDH, mRNA levels were reduced 90%, thus only 10% of the normal number of GAPDH transcripts were present. We observed variation in the transfection of different siRNAs with relative knockdown at 80% for Nrf2 and only 40% for Keap1. Although the level of knockdown of Keap1 was low, it translated to a measurable Keap1 protein reduction, increased HO1 and NQO1 transcription by free Nrf2, and increased cell survival when exposed to prooxidants. The insufficient knockdown of Keap1 may partially explain why tBHQ treatment was able to increase gene expression of ARE-driven genes in the presence of Keap1 siRNA (Figure 18.C). If Keap1 knockdown was complete, all Nrf2 would be free and tBHQ would not be likely to affect ARE-driven gene transcription. The knockdown of Keap1 was sufficient to protect cells against the effects of prooxidants, suggesting that the increase in expression of ARE-driven proteins was

enough to elicit a protective response. We concluded that although Keap1 knockdown was low, it was sufficient to analyze the effect of reduced Keap1 levels.

Another concern using siRNA technology is that of transfection efficiency. Transfection efficiency is expressed as the percentage of cells that take up the siRNA. Transfection efficiency was found to be 42%. While this transfection efficiency is low, gene knockdown specific effects could be detected. These data support the use of siRNA technology in the H9c2 cells and by addressing its inherent limitations (interferon response, transfection efficiency and housekeeping gene normalization) provide us with reasonable assurance that we are using a reliable model with observed due specifically to gene knockdown.

In this study increased gene expression and protein levels of HO1 and NQO1 were observed in response to tBHQ treatment. Activation of Nrf2 by tBHQ and the subsequent increase in expression of stress proteins have been described in numerous tissues (111, 125, 152, 264, 266) and other cell lines (64, 165, 183, 220, 223). Here it is shown that tBHQ activates antioxidant transcription through a Nrf2-dependent mechanism. After treatment with tBHQ a rapid translocation of Nrf2 from the cytoplasm to the nucleus was observed. This translocation occurred within 15 minutes of tBHQ treatment and Nrf2 levels remained elevated in the nucleus for up to 4 hours. This correlates with other studies showing elevated Nrf2 levels from 1-12 hours after activation (89, 173, 222, 310). Similar results were reported in human neuroblastoma cells where tBHQ treatment resulted in dramatic nuclear translocation of Nrf2(167).

Using HO1 and NQO1 mRNA levels as an index of Nrf2-mediated activation of the ARE, Nrf2 knockdown resulted in decreased basal and tBHQ-stimulated HO1 and

NQO1 gene expression. These data suggest that Nrf2 is involved in both basal and stimulated expression of ARE-induced genes. These observations agree with results of studies involving other tissues in which Nrf2 knockout decreased antioxidant-mediated induction of antioxidant genes. For example, in murine prenatal fibroblasts, tBHQ induced HO1 expression in wild-type but not Nrf2 knockout cells, suggesting that Nrf2 is necessary for tBHQ-induced HO1 induction (141). It has also been reported that, in the absence of Nrf2, there is a marked impairment in the expression of genes encoding a number of detoxifying enzymes, including GSH biosynthetic enzymes, in the liver and GI tract (42, 119, 201).

In addition to Nrf2 involvement in ARE-induced gene expression, Nrf2 is also necessary to facilitate the protective effects of tBHQ against cytotoxic effects of oxidative stress.  $H_2O_2$  was chosen because it is a commonly produced ROS in ischemia-reperfusion injury and is more stable than its more reactive counterparts  $O_2^-$  and  $OH^-$  (289). tBHP was chosen because of similarities to the byproducts of lipid peroxidation (207). tBHP has been reported to induce apoptosis in rat hepatocytes (96), HepG2 cells (241) and N<sub>2</sub>A and SH-SY5Y neuronal cells (312) through opening of the mitochondrial permeability transition pore (96, 241).

In the present study, tBHP increased generation of reactive oxygen species and decreased cell viability of H9c2 cells. The effect of tBHP on ROS generation was blocked by pretreatment with tBHQ at the concentration and time frame in which ARE-induced genes are expressed. Additionally, the protective effect of tBHQ on tBHP-induced ROS generation was lost following Nrf2 knockdown using Nrf2 siRNAs. This suggests that Nrf2 activation is necessary for tBHQ-mediated protection of cardiac H9c2

cells. These data agree with many studies demonstrating a relationship between Nrf2 activation and cytoprotection from oxidative stress. Dhakshinamoorthy and Porter (66) reported that siRNA-mediated knockdown of Nrf2 sensitized neuroblastoma cells to NO-induced apoptosis. Nrf2 knockout in primary astrocytes and neurons were more sensitive to oxidative damage and mitochondrial toxins than wild-type cells (164, 168) and overexpression of Nrf2 in astrocytes increased the survival of neurons under conditions associated with non-excitotoxic glutamate toxicity (152). Nrf2 has also been shown to protect the lung from butylated hydroxytoluene-induced acute respiratory distress syndrome (40), hyperoxic injury (47), and bleomycin-mediated pulmonary fibrosis (50) through increased detoxification and antioxidant potentials. Nrf2 knockout mice also show increased sensitivity to acetaminophen-induced hepatotoxicity as well as increased levels of lipid peroxidation and DNA damage (39, 75, 177). These data reinforce the pivotal role of the Nrf2-ARE pathway in protecting multiple tissues and cells from oxidative stress and suggest a universal role for Nrf2 in the protective pathway.

Nrf2 activation is responsible for protection against oxidative stress elicited by tBHQ. Normal cells are susceptible to reactive oxygen species generation caused by H<sub>2</sub>O<sub>2</sub> and tBHP. Pretreatment with tBHQ for 24 hours protected H9c2 cells against H<sub>2</sub>O<sub>2</sub>- and tBHP-mediated reactive oxygen species generation. However, in Nrf2-deficient cells oxidative stress results in an increase in ROS even when pretreated with tBHQ. These data can be interpreted to suggest that the protective nature of tBHQ is due solely to its ability to activate Nrf2, not through the inherent antioxidative nature of tBHQ.

In normal H9c2 cells, Nrf2 activation by tBHQ protects cells against death caused by tBHP and H<sub>2</sub>O<sub>2</sub>. This protective effect is due to the activation of antioxidant enzymes prior to an oxidative event, leaving the cell in a state predisposed for oxidative stress. Upon knockdown of Nrf2, pretreatment with tBHQ did not protect against H<sub>2</sub>O<sub>2</sub> or tBHP, further supporting the idea that Nrf2 is a major player in this protective mechanism. This suggests that Nrf2 is responsible for protection against oxidative stress mediated by both tBHP and H<sub>2</sub>O<sub>2</sub>.

These data are somewhat in contrast to those of Purdom-Dickenson *et al.* (248). They showed that pretreatment with H<sub>2</sub>O<sub>2</sub> protected the cells from subsequent doxorubicin-induced apoptosis, whereas Nrf2 overexpression did not. In an effort to determine if the observed increased survival was mediated through the Nrf2 protein, these investigators overexpressed Nrf2 and treated cells with doxorubicin. Because overexpression of Nrf2 was not protective, the authors concluded that the cytoprotective effect of H<sub>2</sub>O<sub>2</sub> pretreatment is not dependent on Nrf2 activation. They hypothesized that cross talk between Nrf2 and another protein, possibly nuclear factor  $\kappa$   $\beta$ , was responsible for the observed cytoprotection.

In an attempt to clarify the role of Nrf2 in the protective response against oxidative stress we knocked down the inhibitory protein Keap1 using siRNAs. By removing Keap1 it was possible to evaluate the direct effects of Nrf2 in the absence of the activator tBHQ. Keap1 knockdown resulted in low constitutive levels of ARE-containing gene expression, presumably through the constitutive activation of the ARE. In Keap1 deficient cells, the oxidative stressors H<sub>2</sub>O<sub>2</sub> and tBHP had no effect on cell death. These data also suggest that protective effects seen with tBHQ can be attributed

directly to Nrf2 activation. Treatment with Keap1 siRNA mimicked the protective response seen with tBHQ treatment. In the absence of Keap1, Nrf2 is free to activate the expression of antioxidant and detoxifying genes, thus leaving the cell in a protected state. These cells are resistant to the oxidative effects of H<sub>2</sub>O<sub>2</sub> and tBHP at concentrations that are lethal to untreated cells.

To examine the effects of exogenous Nrf2 in protecting the cardiac cells against oxidative stress, H9c2 cells were transiently transfected with human Nrf2 tagged with green fluorescent protein (Nrf2-GFP). Under basal conditions, Nrf2-GFP was localized exclusively in the cytoplasm indicative of nuclear exclusion of Nrf2 and suggesting a negative regulator was preventing nuclear translocation. Furthermore, when Nrf2-GFP cells were treated with tBHQ, fluorescence was localized in the nucleus indicating nuclear translocation of Nrf2. To verify these results we measured transcription of ARE-containing genes. In Nrf2 overexpressing cells, HO1 and NQO1 mRNA remained at basal levels; whereas Nrf2 mRNA and protein levels were elevated. tBHQ treatment resulted in increased HO1 and NQO1 expression, suggesting that Nrf2 is excluded from the cardiac cell by Keap1 or another regulatory mechanism. The observation that Nrf2 translocation and gene transcription occurs only after tBHQ treatment suggests that Nrf2 must be activated in order to protect the cell.

A limitation to the above described experiment is that expression of exogenous human Nrf2 (hNrf2) in rat H9c2 cells may result in problems with nuclear import and ARE-driven gene transcription due to species differences. To evaluate this inherent problem, nuclear translocation of Nrf2 was measured in H9c2 cells. hNrf2 was able to enter the nucleus after tBHQ treatment. tBHQ caused translocation of hNrf2 at the same

concentration and in the same time frame as observed endogenous Nrf2 in H9c2 cells, suggesting that human Nrf2 is able to enter the nucleus of the rat H9c2 cells to initiate gene transcription.

These data can be interpreted to suggest that Nrf2 overexpression was not protective to cardiac cells as described in Purdom-Dickenson *et al.*, 2006 (248). In our experiments, cells overexpressing Nrf2 did not enter the nucleus unless activated by tBHQ. This could explain why Nrf2 overexpression alone was not sufficient to protect the cardiomyocyte against DOX treatment. The observed nuclear exclusion of Nrf2 could be through negative control by Keap1 and/or the nuclear export signal. As indicated in the literature review, the Nrf2 protein contains a redox-insensitive nuclear export signal (NES) (122, 182) and deletion of the NES results in increased localization of Nrf2 after treatment with tBHQ (122). While we did not investigate the contribution of the NES, it is a possible explanation for the observed nuclear exclusion of Nrf2.

Studies discussed in this dissertation are the first to look directly at the effects of Nrf2 in a cardiac model using siRNAs. The use of siRNAs overcomes limitations associated with gene (i.e. loss of function models) knockout mouse because it involved temporary gene knockdown. Knockout mice have many limitations caused by the absence of a gene from the genome at the start of development. Complications include death, chronic health problems, functional compensation by other closely related gene family members, and multiple copies of genes or pseudogenes in genome (239). By temporarily knocking down a gene, siRNA technology reduces the risk of death due to the removal of a protein, reduces the likelihood of functional compensation by other members a protein family and does not discriminate against mRNA created by different

copies of a gene. In fact, development of technology facilitating the use of siRNAs in the whole animal is in progress to bypass the limitations of the knockout mouse (243).

Studies reported here are the first to examine the effects of Keap1 knockdown in a cardiac cell model system. This is especially valuable considering that the Keap1 knockout mutation is lethal in the whole animal. The herein data suggest that reduction of Keap1 actively protects the cardiac cell against lethal levels of prooxidants to an extent similar to that observed for Nrf2 activation by tBHQ. These data suggest that removal of the inhibitory protein Keap1 results in free Nrf2 that translocates into the nucleus initiating gene transcription. This study is also the first to show that overexpressing Nrf2 does not result in nuclear translocation of Nrf2 or ARE-driven gene transcription unless activated by tBHQ. The regulatory mechanism causing nuclear exclusion of Nrf2 is involve both Keap1 and the nuclear export signal.

In summary, Nrf2 was shown to protect H9c2 cells against two forms of lethal oxidative stress associated to exposure to H<sub>2</sub>O<sub>2</sub> and tBHP, through increased antioxidant enzyme levels when stimulated by tBHQ. Activation of Nrf2 is necessary for Nrf2-mediated protection against ROS generation and cell death. Keap1 knockdown protected cells in a similar fashion to that observed with tBHQ treatment, supporting the hypothesis that effects seen after treatment with tBHQ reflect activation of Nrf2 and that Nrf2 must be activated in order to protect cells from oxidative stress. Fluorescent microscopy and gene expression analyses showed that Nrf2 is not present in the nucleus in unstimulated cells overexpressing Nrf2. Thus, Nrf2 overexpression alone does not protect the cell due to retention of Nrf2 in the cytoplasm. From these data it is concluded that Nrf2 protects H9c2 cardiac-like cells from oxidative stress when activated, or in the absence of its

inhibitory protein Keap1. These studies point to Nrf2 as a protective protein that may have therapeutic implications in the fight against cardiovascular disease.

## **CONCLUSIONS**

The Nrf2 protein coordinately activates antioxidant enzymes in many tissues. The role of Nrf2 as a multi-organ protector holds true in the H9c2 cardiac-like cell line. However, Nrf2 must be activated in order to exhibit its protective effects. Removal of Keap1 protects the cardiac like cell from oxidative stress by freeing Nrf2; however the cell exhibits mechanisms that regulate the transcription of ARE-driven genes, which in turn, prevents the overexpression of Nrf2 from being inherently protective. Nrf2 activation protects H9c2 cells against oxidative stress and as such, may be valuable in therapeutic strategies for the treatment of cardiovascular disease.

## APPENDICES

**Appendix A.** A list of compounds reported to activate the ARE.

<b>ARE-Inducers</b>		
1-[2-cyano-3-1,2-dioxooleana-1,9(11)-dien-28-oyl] imdazole	carnosol	lippopolysaccharide
12346 penta O-gallo D-glucose	caroteniods	Low density lipoprotein
17 beta estradiol	chromium IV	mercury
2,3,7,8-tetrachlorodibenzo-p-dioxin	cisplatin	N-3-fatty acid
2,7-dichlorodihydrofluoresceine diacetate	cobalt	Nickel II
3 H-1,2-dimethiole-3-thione	cobalt protoporphyrin	nitric oxide
3-hydroxyanthanilic acid	copper	oltipraz
3-methylcholanthrene	curcumin	organosulfur
3-O-caffeoyl acid	diethylnitrosamine	PD98059
4-hydroxynonenal	deprenyl	pentacholorphenol
acetominophen	diallyl sulfide	peroxynitrate
acetylcarnitine	diesel exhaust	phenolic acid
acrolein	dithiolethiones	phorbol ester
allyl sulfide	ethoxyquin	phytochemicals
alpha lipoic acid	fibroblast growth factor	piperine
antirheumatic gold	flavonoids	polyphenols
apomorphine	garlic	quercetin-glycosides
arsenic	ginkgo biloba	resveratrol
arsenite	hemin	sulforaphane
bis(2-hydroxybenzylidene)acetone	indole-3-carbinol	<i>tert</i> -butyl hydroquinone
bucillamine	Insulin	trans-stibene oxide
butylated hydroxyanisol	isothiocyanates	triterpenoids
cadmium	kainic acid	UV radiation
cadmium chloride	Keratinocyte growth factor	valporic acid
carbon monoxide	lead	xanthohumol

**Appendix B.** Genes reported to be ARE-driven. List generated from Lee et al. 2003. (164)

**Detoxification**

NQO1  
GST A4  
GST Pi2  
GST Mu1  
GST Mu2  
GST Mu3  
Aldehyde dehydrogenase-1  
Aldehyde dehydrogenase-2  
Cytochrome P450 1B1

**Antioxidant/reducing Potential**

GCLM  
GCLC  
HO1  
TXNRD 1  
Ferritin light chain  
Type I peroxiredoxin  
1-Cys peroxiredoxin protein-2  
G6PD, X-linked  
G6PD-2 gene  
Transketolase  
Malic enzyme, supernatant

**Transcription**

Nrf2  
Homeo box, MSH-like 2  
Prolactin regulatory element binding  
CCAAT/enhancer-binding protein-  
Zinc finger protein of cerebellum 3

**Growth**

Colony-stimulating factor-1 receptor  
Ecotropic viral integration site-2  
Insulin-like growth factor-1  
Nerve growth factor-

**Defense/immune/inflammation**

Macrophage C-type lectin  
Cathepsin E  
Cathepsin S  
P lysozyme structural  
Matrix metalloproteinase-12  
Cytotoxic T lymphocyte-associated protein-2  
Cytotoxic T lymphocyte-associated protein-2  
Chemokine (C-C) receptor-5  
Complement component-1q  
Complement component-1q  
Complement component-1qc  
Small inducible cytokine A9  
Small inducible cytokine A27  
Small inducible cytokine subfamily D1  
Integrin 2  
Lysosomal-associated protein transmembrane-5  
Prostaglandin-endoperoxide synthase-2  
Lipopolysaccharide-binding protein  
PAF acetylhydrolase

**Signaling**

Protein kinase C  
Thyroid-stimulating hormone receptor

**Others**

Retinoid-inducible serine carboxypeptidase  
Lipoprotein lipase  
Neoplastic progression-3  
Retinoic acid inducible E3 protein  
Plastin-2L  
Adenylosuccinate synthetase-1  
Esterase-10  
Low density lipoprotein receptor-related protein 2

**Appendix C.** Real-time PCR standard curves for each primer set (HO1, NQO1, GAP, rat Nrf2, human Nrf2, Keap1, 36B4). Standard curves are generated using a 10 fold dilution series of cDNA with primer concentration constant. Each standard curve has a PCR efficiency used by the gene expression macro, and is calculated from the standard curve.

### HO1

### NQO1

## GAP

Correlation Coefficient: 0.999 Slope: -3.245 Intercept: 16.163  $Y = -3.245 X + 16.163$   
PCR Efficiency: 103.3 %

□ Unknowns  
• Standards

## Rat Nrf2

Correlation Coefficient: 0.999 Slope: -3.227 Intercept: 12.223  $Y = -3.227 X + 12.223$   
PCR Efficiency: 104.1 %

□ Unknowns  
• Standards

## Human Nrf2

Correlation Coefficient: 0.990 Slope: -2.921 Intercept: 18.606  $Y = -2.921 X + 18.606$   
PCR Efficiency: 120.0 %

□ Unknowns  
• Standards

# Rat Keap1

Correlation Coefficient: 0.994 Slope: -3.265 Intercept: 20.214  $Y = -3.265X + 20.214$   
PCR Efficiency: 102.4 %

Unknowns  
Standards

**Appendix D:** Cell proliferation assay standard curve. The fit is linear with a correlation coefficient of no less than 0.95.

## Appendix E: List of Abbreviations

15dPGJ2	15-deoxy-delta(12,14)-prostaglandin J(2)
6-OHDA	6-hydroxydopamine
Abrp	acidic ribophosphoprotein
AhR	aryl-hydrocarbon receptor
AP1	Activator Protein 1
ARE	Antioxidant Response Element
ATF2	activating transcription factor 2
ATF4	activating transcription factor 4
BACH	BTB and CNC homology 1
BHA	Butylated hydroxyanisole
BLAST	Basic Local Alignment Search Tool
$\beta$ -NF	b-naphthoflavone
bp	base pairs
cAMP	cyclic adenine monophosphate
Carboxy-H2DCFDA	5-(and 6)-carboxy-2',7'-dichlorodihydrofluorescein diacetate
CAT	chloramphenicol acetyltransferase
cDNA	complementary DNA
CNC	CAP N Collar
CoIP	Co-immunoprecipitation
Cox-2	cyclooxygenase 2
C <sup>P450</sup>	cytochrome P 450
CREB	cAMP Responsive Element Binding protein
CVD	cardiovascular disease
CYP1A1	cytochrome P 450 gene
CYP2E1	Cytochrome P450 2E1
D3T	1,2-dithiole-3-thione
$\Delta\Delta$ CT	delta delta cycle threshold
DEM	diethylmalate
DEPC	diethyl pyrocarbonate
DGR	double glycine repeat
DMEM	Dulbecco's Modified Eagle's Medium
dsRNA	double stranded RNA
EpRE	electrophile response element
ER	endoplasmic reticulum
ERK	Extracellular signal regulated kinase
EtOH	ethanol
FBS	Fetal Bovine Serum
GFP	green fluorescent protein

$\gamma$ -GCS	g-glutamylcysteine synthetase
$\gamma$ -GCS <sub>h&amp;l</sub>	g-glutamylcysteine synthetase heavy and light subunits
GPX	glutathione peroxidase
GR	glutathione reductase
GSH	glutathione
GST	glutathione transferase
H <sub>2</sub> O <sub>2</sub>	hydrogen peroxide
HBSS	Hank's balanced salt solution
HO1	Heme oxygenase 1
hPAP	human placental alkaline phosphatase
HRP	horseradish peroxidase
IgG	immunoglobulin G
JNK	c-Jun N-terminal kinase
Keap1	Kelch-like associated protein-1
LDL	low density lipoprotein
MAPK	mitogen-activated protein kinase
MARE	Maf recognition elements
MOPS	3-(N-morpholino)propanesulfonic acid
MPTP	1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
NES	nuclear export signal
NF-E2	nuclear factor (erythroid-derived 2)
NLS	nuclear localization sequence
NO	nitric oxide
NOS	nitric oxide synthase
NQO1	NADPH quinone oxidoreductase 1
Nrf1	NF-E2 related factor 1
Nrf2	NF-E2 related factor 2
Nrf3	NF-E2 related factor 3
OAS2	2'-5'-oligoadenylate synthetase
PAH	polycyclic aromatic hydrocarbons
PBS	phosphate buffered saline
PCR	polymerase chain reaction
PD	Parkinson's disease
PDTC	pyrrolidin-edithiocarbamate
PI3K	phosphatidylinositol 3-kinase
PEITC	ethyl isothiocyanate
PKC	protein kinase C
Prot 26s	proteasome 26s
RAC3	Nuclear receptor-associated coactivator-3
RISC	RNA-Induced Silencing Complex
ROS	reactive oxygen species
RT	reverse transcriptase

SDS PAGE	sodium dodecyl sulfate poly acrylamide gel electrophoresis
SIN-1	3-morpholinopyrrolidine-N-ethylcarbamate
siRNA	small inhibitory RNA
SOD	superoxide dismutase
TAE	tris acetate EDTA
tBHP	tert-butyl hydroperoxide
tBHQ	tert-butyl hydroquinone
TBS-T	Tris borate sodium tween 20
TE	Tris EDTA
TNF $\alpha$	tumor necrosis factor alpha
TPA	12-O-tetradecanoylphorbol-13-acetate
UV	ultra violet
XRE	xenobiotic response element
