Flotation separation is an important process in mineral processing and paper recycling. Flotation is a separation process used to remove particles from a liquid stream. Bubbles are introduced into the liquid stream, and, as they rise, particles may adsorb to the bubble surface. The bubbles may then carry the particles to the surface of the liquid, where they are removed. This dissertation focuses on flotation deinking. Flotation deinking is used to remove ink particles and other contaminants from recycled paper streams.

Flotation is a complicated combination of fluid mechanics, thin-film dynamics, and surface chemistry. The fundamental process in flotation, the adhesion of a particle to a bubble, was studied using high-speed and high-magnification imaging techniques. Facilities for the study of particle interactions with stationary and flowing bubbles in several different system chemistries are discussed.

These techniques were used to study the interactions between toner ink particles and bubble surfaces. Toner ink particles were observed to adsorb to bubble surfaces. In

the presence of calcium oleate surfactant, toner particle formed networks at the bubble surface. These networks were observed to be very stable. The role of particle size and system chemistry in the adhesion of toner particles to bubbles was examined. Calcium oleate resulted in a larger percentage of bubble coverage than sodium lauryl sulfate chemistry; however, the percentage of bubble surface covered with ink particles did not depend upon the particle size. Estimates were obtained for the volume and mass of toner ink particles attached to the bubble surface. For sodium lauryl sulfate chemistry, the mass of adsorbed toner ink increased from 3.0 mg of ink per bubble for particles less than 75 μm in size to 6.0 mg of ink per bubble for particles with a size range of 250 to 475 μm . When calcium chloride is added to sodium lauryl sulfate surfactant, the mass of adsorbed ink increased. For sodium oleate surfactant with calcium chloride, the mass of adsorbed toner ink increased from 5.9 mg of ink per bubble for particles less than 75 μm in size to 12.5 mg of ink per bubble for particles with a size range of 250 to 475 μm . When the calcium chloride was not used with sodium oleate surfactant, the mass of attached ink decreased. The mass of attached ink particles was largest for the calcium oleate chemistry and increased as particle size increased. No change was seen with the addition of calcium ions to a surfactant-free system. No particle agglomeration was observed in the absence of calcium, suggesting that the proposed “Calcium Bridge” mechanism for particle agglomeration does not occur in this system.

Imaging of model glass beads was also used to study the fundamentals of particle / bubble interactions. The Stokes number (the ratio of inertial forces and viscous drag forces on a particle in a fluid) was used as a criteria to study the mechanism of particle to bubble collision. Particles with a high Stokes number (> 1) were observed to undergo impact collision at the bubble surface. Particles with lower Stokes numbers (< 1) were observed to follow the sliding collision mechanism. These observations confirm the Schulze prediction for the mechanism of collision between a particle and a bubble.

Flotation models were examined for the toner deinking system. Estimates for the probability of particle to bubble collision, probability of particle adhesion, and probability of stable attachment were found experimentally and compared to modeling results. Experimental and data analysis methods were developed to directly measure the

probabilities of the subprocesses from visualization measurements. Model predictions do not match experimental observations. Specifically, estimates for the probability of particle to bubble adhesion were very different from experimental observations.

CHAPTER 1

INTRODUCTION

Adhesion at a solid / liquid / gas interface is controlled by the surface forces and fluid dynamics of the system. Adhesion occurs when a bubble, droplet, or particle of material transfers to and remains at the interface of two other materials due to surface forces. The adhering species has a greater affinity for residing at the interface than for either of the other two phases.

Adhesion is an important phenomenon in several systems. Bubble adhesion to solid substrates in a fluid is important to packed bed multiphase reactors. Liquid droplet adhesion to bubbles is observed in oil flotation and in petroleum exploration. Particle adhesion to a liquid / solid interface is found in many processes including powder manufacture, semiconductor production, and in biological systems. Solid particle adhesion to a gas / liquid interface is important to environmental systems and to slurry-bed catalysis.

The ability of a solid particle to attach to a bubble surface in a liquid is dependant upon the surface properties of the system. For adhesion to occur, a three-phase contact must exist such that the attractive and repulsive forces of the solid species are in equilibrium. Often, the liquid is an aqueous solution and the bubbles consist of air. An adhering particle will therefore be at least slightly hydrophobic; that is, it will prefer the

air phase to the water phase. Wastewater treatment processes take advantage of this phenomenon to remove suspended particulates from water streams.

Flotation processes remove particles from a water system by introduction of air bubbles. The bubbles rise by buoyancy, and suspended particles adhere to the bubble surfaces. The net effect is a transport of particles to the top of the fluid, where they may be removed. As the particles and bubbles are in relative motion, the short-range hydrodynamics of the system are as important to adhesion as the surface phenomenon.

Particle to bubble attachment can be modeled as a series of subprocesses. Each of these subprocesses has a probability of occurrence, so that the overall probability of adhesion of a particle to a rising bubble, P , is defined as

$$P = P_C \cdot P_A \cdot P_{TPC} \cdot P_{Stab} \quad (1)$$

where P_C is the probability of bubble particle collision, P_A is the probability of particle attachment, P_{TPC} is the probability of the formation of a stable three-phase contact, and P_{Stab} is the probability that an adsorbed particle will remain stably attached. The first and second of these probabilities depend strongly on the fluid dynamics of the system, while the third and fourth probabilities depend upon the surface phenomena.

This work explores the interactions of particles with bubble surfaces using high speed and high magnification imaging. The effect of important flotation parameters, such as particle size and flotation chemistry, is examined by direct observation of their impact on the attachment of particles to bubble surfaces. Each of these adhesion subprocesses is observed in order to gain a better understanding of their role in flotation, and to allow evaluation of the available flotation models. This research aims to improve the

understanding of particle to bubble attachment in flotation systems by expanding the experimental knowledge of the phenomena.

CHAPTER 2

BACKGROUND

This document presents the development of and results from techniques to image and quantify the parameters and fundamental processes important to flotation. The hypothesis is that the flow behavior of the fluid between the particle and the surface of the bubble plays a role as important as the surface properties of the system. The research approach is that by analyzing high spatial and temporal resolution images the fluid flow and surface processes governing the adsorption of particles onto bubble surfaces can be examined. This document describes the application and advancement of the methods developed by Davies [2000, 2002] for study of the adsorption of ink particles, and it provides quantitative study of the effects of system parameters on flotation and the effectiveness of the subprocesses involved. These techniques are used to demonstrate a systematic method for evaluating the effectiveness of froth flotation and dissolved air flotation (DAF) for processes relating to the recycling of post-consumer paper products. The optical methods are also shown to be useful in evaluation of the fundamental subprocesses at work in flotation.

2.1 Paper Recycling Overview

The importance of fiber recovery has grown dramatically in recent years as the demand for recycled paper has grown. According to the 2000 RPA Federal Timber

Assessment (USDA, 2000), recycled materials are expected to be the fastest growing source of papermaking fiber through 2050; recycled fiber production is expected to increase 130% from 42 to 94 million tons per year. Twenty-nine states and the federal government have mandated minimums on the purchase of recycled paper for government services.

An important, and difficult, step in the recycling process is the removal of contaminants from the repulped fiber slurry. This must be done to improve the recycled paper product and for process viability reasons. Common contaminants include many different forms of ink, stickies (adhesives and other polymers found in stamps, tape, and paper coatings) and filler (non-fiber paper material used to increase brightness and printability). Ink particles in the mill process water redeposit onto fibers causing specks and a drop in brightness. Agglomerated stickies particles plug holes in screens, deposit on the paper machine wire, and can cause paper strength quality issues when deposited onto paper fibers. Contaminants are often classified by their method of removal.

Figure 2-1 presents an overview of a typical paper recycling process. The first step in the recycling process is the repulping of the reclaimed material. The paper is sent to the repulper where it is mechanically agitated and cut in water to form a slurry. Often, all of the chemicals needed for the recycling process are added at this stage due to the large degree of mixing in the repulper. The slurry is then sent through banks of screens: the course screens remove large debris such as sand and dirt, paperclips, and staples from the slurry; the fine pressure screens remove light contaminants such as large stickies particles. The pulp slurry may be cleaned using centrifugal cleaners. The pulp is then processed with flotation deinking. This step uses bubbles to remove hydrophobic

contaminants (such as oil-based inks, toner inks and polymeric contaminants) from the fiber surface and from the suspension water. The pulp is then washed to remove soluble contaminants to make it ready for use in papermaking.

The washing step involves removing ink and other contaminants from the fiber using sodium hydroxide, sodium silicate, and hydrogen peroxide; these chemicals are often added in the repulping unit. A dispersent is often used to prevent redeposition of contaminants onto fibers; micelle formation is usually induced with stearic acid, causing the grease and oil binders of the ink to become dispersible in water. The fibers can then be separated from the wash water, which can then be treated by dissolved air flotation to allow reuse of the water. [Smook, 2002] The wash water may then be sent through a dissolved air flotation step to prepare it for use in the repulper and other mill processes. The effectiveness of the recycling operation is evaluated by testing the optical and strength properties of the recovered pulp.

Thickening and bleaching bring the pulp slurry to the state in which it can be used to manufacture the product. Thickening is the dewatering of the pulp slurry to bring its consistency to a value useful for papermaking. Bleaching is used to increase the brightness of the pulp; this operation is especially important for copy paper, newsprint, and tissue where the “whiteness” of the paper is very important.

Figure 2.1: Illustration of the paper recycling process.

2.2.1 Flotation Processes

The first patent for a flotation deinking process was granted in 1933 (Hines, 1933). The first domestic commercial flotation deinking plant opened in 1955, with the first European plant following in 1959. In 1992, it was reported that there are approximately 325 flotation deinking plants worldwide (Poyry, 1993).

There are two forms of flotation common to the recycled paper industry: froth flotation and dissolved air flotation. Froth flotation, sometimes called induced air flotation (IAF), is the injection or production of air bubbles into a vessel to remove contaminant particles. The particles adsorb onto the surface of the bubble and float to the top; they are then skimmed off to separate the floated particulates from the water. IAF usually yields bubbles between 1.0 and 2.0 mm in diameter. IAF cells are best suited to remove large hydrophobic contaminants (from 100 to 500 μm). This form of flotation is well established in the mining industry (Gaudin, 1957; Leja, 1982) to separate fine or precious metals from ore-stock and also has seen use in the petrochemical industry for removal of oils from water (Zheng and Zhao, 1993). Typical IAF processes involve an air jet impinging upon a high speed impeller in the bottom of the flotation vessel. The air stream is broken up into bubbles. Nozzle flotation is a specialized froth flotation process which produces bubbles of 400 to 800 microns. The contaminated flow is mixed with air and is injected into the flotation vessel. Bubbles are produced as the air water mixture is sprayed into the vessel. This process has the advantage of fewer moving parts when compared to typical IAF processes (Gopalratnam et al., 1988). In paper recycling, froth flotation is used to separate ink and other contaminants from the pulp slurry water and also from the fiber surface. Some fiber is lost in the froth layer in this process.

Another flotation process is dissolved air flotation (DAF). DAF units involve putting the contaminated water under pressure. The stream is saturated with air. A pressure drop in the system causes the excess air to leave solution, forming very small (30 – 200 μm) bubbles. These small bubbles collect contaminant particles and float them to the top. DAF cells are more suited to remove smaller sized contaminants than those found in froth flotation units.

DAF is used to remove particles in many applications. It is used to clarify wastewater, separate solids from potable water, separate biological flocs and algae, remove ions and charged metal complexes, and separate very fine particles of similar density (Rubio et al. 2002). The DAF unit is used in the paper recycling process for process water clarification. The process water from the washing of the secondary fibers contains ink and other small particulates, which are removed by a DAF unit. Unlike a froth float cell, a DAF cell operates on a largely fiber free water stream (Smook, 2002). DAF is also widely used for water clarification in other industries.

Typical froth flotation separation processes consist of a complicated system of multiple banks of several flotation cells. Each bank may serve a specific separation purpose (e.g. removing large contaminants, cleaning of a dilution stream or scavenging of recycle stream). An example froth flotation circuit used by Minera Escondida Ltd. in Chile consists of 6 banks of 9 flotation cells (Yianatos et al. 2005). Rubio et al. (2002) present an excellent overview of the various forms of flotation equipment.

Other forms of flotation are used in niche applications in other industries. Electro-flotation involves the production of micro-bubbles of hydrogen via electrolysis in the flotation cell. Aqueous waste is passed through the cell over embedded electrodes

(often aluminum) which produce micro-bubbles of hydrogen gas. The hydrogen bubbles collect solid contaminant particles and rise to the surface of the cell, just as in IAF and DAF. Problems associated with electro-flotation include cost and maintenance of electrodes and dangers associated with the production of hydrogen gas. This process has seen industrial use in the removal of emulsified oils, toxic ions, and pigments from water (Zabel, 1992; Zouboulis 1992a, 1993). Electro-flotation has been proposed by Zouboulis for use in deinking, but no applications of such are known.

The fundamental mechanisms of flotation are common to both froth flotation and DAF, and for all forms of flotation. The processes differ in the manner in which bubbles are created, in bubble size, and in size of particulates suited for removal, but each is governed by the fundamental behavior of a particle at a bubble surface. A better understanding of this fundamental behavior therefore has potential for improvement of wastewater treatment as a whole. Of particular interest is the flotation of non-impact inks (toners), flexographic inks and polymeric contaminants in de-inking flotation.

2.2.2 Contaminants Removed by Flotation

There are several different kinds of contaminants targeted for removal in the flotation cells of a paper recycling process. The major categories are dirt and other trace material, inks, and stickies. Dirt and sand are often found when recycled paper is repulped. Due to their relatively large size and large density, dirt particles are usually very easy to remove. Most dirt is removed by the pre-flotation screens and cleaners. The amount of dirt present often determines the number of froth flotation cells needed to

properly clean the fiber, as well as the degree of washing required. Dirt is not particularly difficult to remove from the fiber or from the wash water.

Stickies are polymeric contaminants found in recycled paper. Typical sources of stickies include stamp and envelope adhesives, magazine coatings, and hot melt glues. If stickies are not removed effectively from the wash water, they will cause problems in other parts of the papermaking process. Stickies can plug screens in a paper mill, as well as the papermaking wire. Also, stickies can redeposit onto the fiber creating paper strength issues. Stickies can be water dispersible and hydrophobic.

Inks can be categorized into two types: hydrophobic and hydrophilic inks. All black inks are made up of carbon black with a binder that attaches them to the paper surface. Examples of hydrophobic inks are offset inks and toner ink. They are difficult to remove from fibers. However, their hydrophobic nature causes them to be very easy to remove from water using flotation deinking and DAF.

An example of a hydrophilic ink is flexographic ink. Flexographic ink is used because of its ability to be easily cleaned from printing presses and the absence of the need for volatile organics in the printing and cleaning process. Its hydrophilic nature allows presses using it to be cleaned with water, instead of the harsh organic solvents used to clean offset ink. Flexographic ink responds poorly to deinking flotation and once in the wash water is very difficult to remove. Most recycle plants limit the amount of flexographic printed paper they accept due to this problem in removing it from process water. The clarification of water containing flexographic ink is a key problem in the expansion of paper recycling.

Toner ink is a non-impact ink used in personal computer printers and in xerography machines. It is primarily found in mixed office waste (MOW). Mixed office waste accounts for 6-10 percent of the commercial solid waste stream; MOW is 3 percent of the total solid waste stream in the United States (WMD-SW-13, 1998). Toner printed papers account for a relatively small fraction of reclaimed fiber; in 2005 1.4 million tons of printing and writing papers were recovered, compared to 51 million tons of total reclaimed paper products (Franklin Assoc., 2006). The increasing amount of MOW being used for recycled pulp and the increase in the use of the personal printers has led to a desire to improve the floatability of toner inks.

Toner inks are a combination of a carbon black pigment and a resin binder. A typical toner resin is poly (methyl methacrylate) or poly (acrylic acid) (Ferguson, 1995). In printing the resin is heat-set or photo-set and forms a solid printed layer on the paper surface. The toner, once set, is very difficult to remove from the fiber surface. When the toner is dislodged from the fiber during recycling, it forms relatively large flat flakes (Theander and Pugh, 2004). The size of the released particles depends on a number of factors in the repulping system, including system pH, presence of surfactants, and type of repulping equipment (Miller et al., 1999).

2.2.3 Flotation Chemistry

The chemistry of a deinking flotation cell is very complex. In addition to pulp fibers, fillers, and contaminants, many different process chemicals are present. Each step in the recycling process requires the addition of different chemicals. Washing agents, fiber

conditioners, coagulants, dispersants, foaming agents, bleaching chemicals, and surfactants may all be found in a flotation cell (Fergusson, 1992).

Surfactants play a key role in deinking operation. They aid in removing ink from the fiber surface by helping to dislodge ink from paper in the repulper. They also help in washing by keeping the ink particles suspended in the wash water and preventing redeposition of ink onto fiber. They can be used as collectors in the flotation cell by causing ink particles to agglomerate. Surfactants can also serve as foaming regulators in the flotation cell by controlling the stability of the froth. Often, a single surfactant is chosen to perform all of these tasks (Ferguson, 1992). Several of these roles are competing and contradictory (e.g. dispersant vs. collector, or frother vs. defoamer). Surfactant choice and dosage must therefore be carefully studied.

Surfactants in the flotation cell directly impact the flotation efficiency. Decreased surface tension at the air bubble / water interface allows particles to more readily adsorb, but also decreases adsorption stability. Collector chemicals may cause agglomeration of particles, affecting the average particle size. Dispersing agents can prevent particle to bubble adsorption by making the particle (now a particle / surfactant molecule complex) more hydrophilic.

Deinking flotation is performed in a basic system (pH often ~9.5) and the targeted contaminants (inks) are polymer based materials, so anionic or non-ionic surfactants are usually used. Two common surfactant types in flotation are fatty-acid based soaps and sodium silicate / sulfonic acid based surfactants.

Fatty-acid soaps, such as calcium oleate, are often used in flotation to promote ink particle agglomeration. Particle agglomeration serves two purposes. First, small particles may be prevented from forming colloidally stable dispersions by agglomeration. Second, small particles can form larger flocs which may aid in flotation. Sodium silicate and sulfonic acid based surfactant systems, such as sodium lauryl sulfate, are used in paper recycling as dispersants. Dispersants (also called wetting agents or detergents) cause particles to be more stable in water and prevent particle to particle agglomeration or particle deposition on the fiber surface. They therefore aid in pulping and washing operations. An unwanted side effect of dispersants is hindered flotation by reducing particle size and the hydrophobicity of the particles (Fergusson, 1992). Sodium silicate also serves as a chelating agent by precipitating large metal ion complexes from the repulper.

Using surface force and coagulation measurements, Pugh and Rutland (1997) investigated the mechanisms of particle agglomeration in flotation deinking. Figure 2.2 presents the three proposed mechanisms: a.) Direct calcium ion bridging between ink particles b.) Particle agglomeration by precipitation of calcium soap at the particle surface and c.) Destabilization of ink particles by calcium ions. Their work suggests that, while the surfactant ions do not promote particle agglomeration, surfactant salts can precipitate on the particle surface and act as “bridges” between particles. These proposed mechanisms of particle agglomeration will be discussed in Chapter 5.

Fatty-acid soaps increase the particle size of flotation contaminants, and increase the three phase contact angle between the particle / air / water solution. Sodium silicate / sulfonic acid based systems lower the contact angle. Both surfactant systems lower the

surface tension. The role of these parameters in flotation modeling will be presented in Section 2.5.

Fig. 1. Possible mechanisms involved in calcium soap deinking.

Figure 2.2: Proposed mechanisms of the role of calcium ions and surfactants in ink particle agglomeration (Pugh and Rutland, 1997).

2.3 Previous Work of the Research Group

Previous work by this research group on flotation includes the work of Davies (2000, 2002), Rossi (2000), Bonometti (2001, 2006), Emerson (2003, 2006), and Ham (2004). Davies and Rossi designed and built the experimental apparatus used for most of this work: the stationary bubble facility and the suspending bubble flow facility. They created the procedure for suspension of bubbles in a flotation flow field and determined that, in the presence of surfactant, the flow around a suspended bubble most resembled the flow around a rigid sphere. They also developed the protocol for creating the image sequences of particle adsorption. Davies work involved the flotation of flexographic and offset inks (Davies et al. 2000, 2002). Flexographic ink was not seen to adsorb to the bubble surface in either of the experimental systems used.

Bonometti extended the work of Davies and imaged the behavior of toner inks at bubble surfaces. Toner ink was seen to adsorb very well to bubble surfaces. Toner ink was also seen to form networks of toner particles, and these particle networks were shown to be extremely stable. He developed a method by which the amount of ink adsorbed at a bubble surface could be estimated from image data. He calculated the percent of bubble coverage and mass of adsorbed ink over time for toners and for offset inks (Bonometti 2001, Emerson et al. 2006). Ham studied the effect of enzymes on the flotation of toner inks. He demonstrated that enzymes can improve the flotation removal of toner ink from repulped fiber and performed the first imaging of flotation processes in the presence of fiber (Ham, 2004).

We have also imaged the adsorption of stickies particles. A method to evaluate the adsorption of pressure sensitive adhesives to bubble surfaces was developed by

processing of images from high-speed video sequences. Coagulated stickies particles were seen to adsorb strongly to bubble surfaces in both the stationary bubble facility and in the suspending bubble flow facility. The adhesion of stickies particles was shown to be very stable (Emerson 2003).

2.4 Previous Imaging of Particle Bubble Adsorption

Other authors have used imaging to study the adsorption of particles to bubble surfaces. Thompson et al. (1997a, 1997b) studied the adsorption of toner particles to stationary bubbles. He observed that large flat toner particles adsorb to bubbles by small sharp points. Kim et al. (2004) used CCD imaging to study the interaction of stickies particles with bubbles in the presence of fiber. They demonstrate that the mass of adsorbed stickies particles increased as the residence time of the bubble in cell increased, similar results to those of Bonometti for toner ink. They also showed that calcium fatty acid chemistry allows much more adsorption of stickies than clear water chemistry, consistent with observations for toner ink in our laboratories (Emerson et al. 2006).

Nguyen and Evans (2004) used high-speed imaging to observe the behavior of model hydrophobic spheres at a bubble surface. They used high-speed movies to determine the polar position for colliding particles over time in order to investigate the flow phenomena around the particle. By determining when the particle ruptures the thin liquid film around the bubble, they postulate that surface forces do not play as active a role in particle adsorption as previously believed. The authors use their measurements to determine the induction time of a particle at a bubble surface. The induction time, or

particle to bubble contact time, is the minimum time a particle must slide along a bubble surface for adhesion to occur by drainage of the film between the particle and the bubble.

Other imaging of bubble / particle interactions investigated the increased mass transfer properties observed in gas slurry reactors. When sufficiently small catalyst particles are used, an increased reaction rate is observed; this increase is thought to be due to better mass transfer among the three phases in the reactor. Wimmers and Fortuin (1988) postulated that the cause of the increase is adhesion of catalyst particles to the gas liquid interface. Vinke et al. (1991, 1993) confirmed this by using equilibrium imaging of adsorption of catalyst particles adsorbed to different gas bubbles (hydrogen, argon, and oxygen) in aqueous solution. Using equilibrium images to measure the maximum polar angle of bubble coverage and performing a force balance on the adsorbed particles, the authors developed an expression for the three phase contact angle, a difficult to obtain parameter useful in flotation modeling. Roizard et al. (1999) performed similar dynamic experiments and found that for some catalyst / gas systems no adsorption occurred, but increased mass transfer is observed. Bliet et al. (2001) found that hydrogen gas was superior to nitrogen gas which was superior to air in causing carbon particle adhesion to bubbles. This was a surprising result, suggesting that electrostatic properties of the bubble or particle are not as important to fostering adsorption as thought.

2.5 Flotation Modeling

The process of flotation combines fluid and particle mechanics, thin film theory, and surface science. Many of the isolated fundamental phenomena are well developed theoretically, but there is little overlap between theoretical developments, experimental

work and industrial observations. Most experiments consist of comparison to bench-top or pilot-scale flotation cell results, with little experimental examination of the fundamental processes at work. An understanding of the fundamentals of flotation is needed in order to evaluate the results of experiments or to propose changes to published models. This section will present the development of the current state of flotation modeling, with emphasis on the description of the individual subprocesses at work.

For years, flotation has been modeled as a series of subprocesses. Each of these subprocesses is characterized by a probability of occurrence; the probability of the successful flotation of a single particle by a single bubble is therefore described as the product of the probabilities of the individual subprocesses (Woodburn, 1970). The overall probability of flotation is

$$P = P_C P_A P_{TPC} P_{Stab} \quad (1)$$

where P_C is the probability of particle collision by a bubble, P_A the probability of attachment of a particle to a bubble, P_{TPC} is the probability of the formation of a stable three-phase contact, and P_{Stab} is the probability of stability of the bubble / particle complex. This form of the flotation model has become accepted to the point that the modeling has become focused on development of models for probability of the separate subprocesses. The various models for each subprocess and their combination to form a single kinetic model for flotation operation will be discussed.

Several assumptions are uniform throughout this development and review of flotation modeling. The different subprocesses are assumed to be independent of each other. The models assume spherical bubbles and particles. The flow around the bubble is modeled as if the bubble were stationary in a flow field giving the equivalent bubble

rise velocity. The particle is assumed to be smaller than the bubble. Also, the models assume only one particle interacts with each bubble. The validity of these assumptions will be discussed.

2.5.1 Probability of Particle Interception (Collision)

The first subprocess of interest is the interception of the particle by the bubble. This probability is an indication of the particle moving into range of the bubble surface where surface forces and thin-film phenomena become important. Other terms used for this subprocess are probability of capture and probability of collision. For a bubble particle collision to occur, the particle must travel towards a bubble (with radius R_B) in a streamline that lies within a capture radius, R_C , from a vertical line from the bubble center, as shown in Figure 2.3. Collision probability between two spheres, P_C , was defined by Sutherland (1948) as

$$P_C = \left(\frac{R_C}{R_B} \right)^2 \quad (2)$$

The difficulty therefore becomes estimating the capture radius.

Figure 2.3: Diagram of capture radius. Particle to bubble collision occurs when a particle enters on a streamline within R_C .

2.5.1.1 Collision with No Particle Inertia

The probability of collision derived from stream functions by Gaudin (1957), with the assumption of Stokes flow at the bubble and particle surface and very small bubbles (inertia effects of the particles were ignored), was

$$P_C = \frac{3}{2} \left(\frac{R_P}{R_B} \right)^2 \quad (3)$$

where R_P is the particle radius. Yoon (1991) found this model to be applicable for bubbles smaller than 100 microns in diameter, which is unsatisfactory for flotation modeling due to the assumption of very small bubble sizes. Reay and Ratliff (1987) used numerical solutions of the Navier-Stokes equations to derive

$$P_C \propto A \left(\frac{R_P}{R_B} \right)^n \quad (4)$$

which indicates a power law relationship between the ratio of particle and bubble size and the probability of collision with coefficients A and n . They also indicate that the collision is a function of the flow behavior of the particle and bubble, e.g. the Reynolds number of the bubble, Re_B . Weber and Paddock (1988) used the power law relationship and numerical methods to derive expressions for A and for n to obtain

$$P_C = \frac{3}{2} \left(1 + \frac{\left(\frac{3}{16} \right) Re_B}{1 + 0.29 Re_B^{0.56}} \right) \left(\frac{R_P}{R_B} \right)^2 \quad (5)$$

which was the first collision model to apply for wide ranges of particle and bubble sizes. Yoon et al (1999) used stream functions for intermediate Reynolds numbers to obtain

$$P_C = \left(\frac{3}{2} + \frac{4 Re_B^{0.72}}{15} \right) \left(\frac{R_P}{R_B} \right)^2 \quad (6)$$

Yoon reports that, despite the functional difference in these relations, the predicted probabilities from both models closely match one another (2000). Note that both models agree with Gaudin in that they reduce to equation (3) for low Reynolds number (Stokes flow). Nguyen (1994) presents collision probabilities from several different sources for many sets of Reynolds number values.

2.5.1.2 Collision with Particle Inertia

The preceding developments assume that, since particle mass density is often low, particle inertia can be ignored. The particles are therefore assumed to closely follow the streamlines around the bubble. If particle inertia is high, as is always the case in mineral

flotation, impact collision can occur. The particles will directly strike and deform the bubble surface. For adsorption to occur in these circumstances, the attractive surface forces must stabilize before the particle is repelled by the reformation of the bubble. Particles with a very small Stokes number are dominated by streamline contact (they follow the streamlines around the bubble), and large Stokes numbers are controlled by impact collisions. The collision of particles with intermediate Stokes numbers from 0.001 to 1, the intermediate range reported by Schulze (1984), will be controlled by both mechanisms. Deinking particles usually have very small Stokes numbers due to their small size and small density.

$$St = \frac{\rho_P d_P v_B}{9 \mu_l d_B^2} \quad (7)$$

Here, ρ_P and d_P are the density and diameter of the particle, v_B and d_B are the rise velocity and diameter of the bubble, and μ_l is the viscosity of the water. Typical Stokes number values for spherical glass particles in water (25° C) are 0.003 for a particle diameter of 75 μm and 0.55 for a particle diameter of 450 μm . Schulze (1989) proposed that the contributions of interception collision, gravitational collision, and inertial collision are additive to obtain the overall collision probability as shown in equation (8).

$$(P_C)_{Overall} = P_C + E_g + \left[1 - \frac{E_C}{\left(1 + \left(\frac{R_P}{R_B} \right)^2 \right)} \right] \cdot E_{In} \quad (8)$$

Here, P_C is the probability of sliding, or incident, collision as described in section 2.5.1.1, E_g is a term representing the contribution of gravitational motion, and E_{In} represents the

contribution of inertial forces. The effect of inertia is therefore to shift the path-line followed by the particle toward the bubble surface. The effect of gravity is expressed as

$$E_g = \left(1 + R_p/R_B\right)^2 \left[\frac{v_P/v_B}{\left(1 + \frac{v_P}{v_B}\right)} \right] \sin^2 \phi_c \quad (9)$$

where v_P and v_B are the terminal settling and rising velocities of the particle and bubble, respectively and ϕ_c is the critical tangential flow angle, defined by as

$$\phi_c = 78.1 - 7.37 \log(\text{Re}_B) \quad (10)$$

for $20 < \text{Re}_B < 400$

The inertial effects were defined, in terms of the Stokes number as

$$E_{in} = \left(1 + R_p/R_B\right)^2 \left[\frac{St}{(St + a)} \right]^b \quad (11)$$

with a and b being system parameters depending upon the Reynolds number of the rising bubble.

Dai et al. (1998) modified the work of Dukhin (1982) to develop a separate relation for collision taking into account the inertial forces and the centrifugal action on the particle as it slides around the bubble. Dukhin (1982) used a parameter called the angle of tangency, which is the polar location where the centrifugal force and the inertial force cancel each other, to combine the effect of each in the probability of particle capture:

$$\theta_c = \arcsin \left\{ 2 \beta \left[(1 + \beta^2)^{0.5} - \beta \right] \right\}^{0.5} \quad (12)$$

$$\text{where } \beta = \frac{2}{3 \cdot St} \cdot \frac{R_p}{R_B}$$

Equation 8 becomes

$$P_C = \frac{3R_p}{R_B} \cdot \sin^2 \phi_t \cdot \exp \left\{ 3 \cdot St \left[\cos \theta_t \left(\ln \frac{R_B}{R_p} - 1.8 \right) - \frac{2 + \cos^3 \theta_t - 3 \cos \theta_t}{6 \left(\frac{R_p}{R_B} \right) \sin^2 \theta_t} \right] \right\} \quad (13)$$

This analytical expression was developed from the combination of viscous drag on the particle as it slides around the bubble with the inertial and centrifugal forces at work on the particle.

While the theoretical background on the subprocess of particle interception is well developed, little experimental work has been performed. Dai et al. (1998) performed flotation cell experiments using extremely hydrophobic particles which were assumed to have attachment and stability probabilities of unity. The effectiveness of the flotation was therefore directly related to the probability of collision. The results were compared to model predictions from several different authors. They observed that, while the models predicted the general functional behavior of the collision probability, only the modified Dukhin equation (1998) closely matched the experiments. However, the experiments were performed for very small, relatively dense particles, which are outside the purview of many of the models examined and not generally applicable to flotation deinking.

2.5.2 Particle Attachment to Bubble Surface

The probability of collision only denotes that a particle has a chance to adsorb to the bubble surface. The probability of a particle to adsorb to the bubble surface is the least explored subprocess in flotation. Two mechanisms for particle adsorption are

possible. The particle may slide around the bubble surface along a streamline; as it slides, the aqueous film between the particle and the bubble can thin and eventually rupture. If the film thins to some critical value, the particle will adsorb to the bubble surface. The particle also may directly impact the bubble surface. As the particle strikes the bubble, the bubble is deformed. If a stable contact is achieved before the particle is repulsed by the reformation of the bubble surface, adsorption will occur. Both mechanisms will be discussed.

2.5.2.1 Particle Adhesion by Sliding

For a particle to attach, it must slide along the bubble surface and the thin aqueous film at the surface must drain to some critical thickness, h_{Crit} , as shown in Figure 2.4. A particle approaching the bubble in a streamline that lies within R_{Crit} will reach this film thickness. Similar to the development of Sutherland (1948) the probability that a particular particle will do this then becomes

$$P_{ASL} = \frac{R_{Crit}^2}{(R_B + R_p)^2} \quad (14)$$

and can be expressed in terms of the critical angle as

$$P_{ASL} = \sin^2 \phi_{Crit} \quad (15)$$

The critical film thickness, and therefore the critical angle, depends upon the surface and hydrodynamic forces of the system. The forces at work include the weight of the particle, the centrifugal force as the particle slides around the bubble, the flow force due to the streamlines, the drag force opposite to the flow, and the resistive force of the film draining. These are all very complicated and interconnected and thus very difficult to

find from base principles. In general terms, it can be seen that the critical film thickness will be higher for systems which allow adhesion. This film thickness corresponds to the minimum distance where the attractive forces of the bubble surface on the particle will counter the forces which act to move the particle past the bubble (Bloom 1997).

Figure 2.4: Diagram of attachment by sliding parameters. Particle must approach within h_{crit} from the bubble surface for attachment to occur.

The critical angle is extremely difficult to measure experimentally. Bloom and Heindel (1997) describe a process to calculate the angle by integrating the sum of the forces acting on the particle over time. The behavior of the thin film between the bubble and the particle is modeled to yield an expression relating the critical film thickness to the maximum of the critical angle. This is only useful if experimental data is available for the critical film thickness, which is as difficult to observe as the critical angle.

Other authors have proposed formulations for the probability of adhesion by sliding based upon flow and fluid parameters. The development of Yoon et al. (2000):

$$P_{ASL} = \sin^2 \left\{ 2 \arctan \exp \left[\frac{-(45 + 8 \text{Re}_B^{0.72}) v_B \tau_i}{30 R_B \left(\frac{R_B}{R_P} + 1 \right)} \right] \right\} \quad (16)$$

applies for intermediate Reynolds numbers. The authors avoid the problem of determination of the critical angle by using a parameter, τ_i , which is the minimum induction or sliding time of the particle needed to cause attachment. Much flotation research involves determination of this induction time analytically or experimentally (Gu et al., 2003 & 2004; Peng, 1996; Yoon et al., 2000).

2.5.3 Probability of Formation of Three-Phase Contact

Once the thin film has ruptured, three-phase contact points must form between the bubble, particle, and liquid. A contact point must form quickly to prevent the particle from immediately detaching from the surface. Schulze (1984) proposes that the turbulent vortices in the cell are the main source of disruption of this formation and that for formation to occur, the time needed to form the three-phase contact, τ_{TPC} , must be less than the average lifetime of the turbulent vortices, τ_v . He proposes that the probability of this formation has the form

$$P_{TPC} = 1 - \exp \left(\frac{-\tau_v}{\tau_{TPC}} \right) \quad (17)$$

Schulze also shows that this probability is equal to 1 for many particles sizes. Indeed, most authors neglect this probability in their models (Heindel & Bloom, 1997; Dai et al. 2000; Yoon, 1991).

2.5.4 Probability of Attachment Stability

If attachment does occur, a particle must remain adsorbed to the bubble surface in order to be successfully floated. The probability of attachment stability is also complicated, but can be developed by performing a force balance on the adsorbed particle (Heindel, 1997). It is generally assumed that the particle has moved to the bottom of the rising bubble surface. The experimental work of Plate (1991) shows that the probability of stability has the functional form

$$P_{Stab} = 1 - \exp\left(1 - \frac{1}{Bo'}\right) \quad (18)$$

where Bo' is the modified Bond number as defined by Schulze (1989):

$$Bo' = \frac{F_{Detach}}{F_{Attach}} \quad (19)$$

The important parameter therefore is the ratio of the forces of detachment, F_{Detach} and the forces of attachment, F_{Attach} . The forces of attachment include the apparent weight of the particle, F_{Wt} , the drag on the particle from the incident flows, F_D , and the capillary force on the bubble side due to surface tension, F_σ

$$F_{Detach} = F_{Wt} + F_D + F_\sigma \quad (20)$$

The forces of attachment consist of the capillary force on the liquid side, F_{Ca} , and the hydrostatic pressure force, F_{Hyd} :

$$F_{Attach} = F_{Ca} + F_{Hyd} \quad (21)$$

These forces and their directions are summarized in Figure 2.5 (Heindel 1997).

Figure 2.5: Illustration of the forces of attachment and detachment important to the probability of particle adhesion stability.

The apparent weight of the particle combines the gravitational force on the particle and the buoyancy force of the liquid on the particle. For spherical particles, it is expressed by

$$F_{wt} = \frac{4}{3} \pi R_p^3 (\rho_p - \rho_l) g \quad (22)$$

The drag force is caused by the flow friction which is due to the local fluid motion in the flotation cell.

$$F_d = \frac{4}{3} \pi R_p^3 \rho_p a_c \quad (23)$$

Schulze assumes that only the centrifugal acceleration, a_c , due to turbulent eddies is significant so that the acceleration term in the drag force becomes

$$a_c = \frac{1.9 \varepsilon^{\frac{2}{3}}}{(R_B + R_p)^{\frac{1}{3}}} \quad (24)$$

Here the turbulent energy density, ε , is necessary to calculate the drag force. For a typical flotation cell, Schulze gives this to be between 10^{-3} and 10^{-1} kW/kg or 10^4 to 10^7 mm^2s^3 (1984). The capillary force on the bubble surface, F_σ , is the measure of the tendency of the bubble to minimize its surface area. The bubble / water interface contracts, which ejects the particle from the three-phase contact point. This force is given by the following:

$$F_\sigma = \pi R_p^2 \left(\frac{2\sigma}{R_B} - 2R_B \rho_l g \right) \sin^2 \omega \quad (25)$$

Here σ is the interfacial surface tension between the liquid and gas and ω is the angle shown in Figure 2.6.

Figure 2.6: Illustration of stably adsorbed particle at the bottom of a bubble.

The attachment forces consist of the capillary force on the liquid side and the hydrostatic pressure force due to the thin film surrounding the bubble. Most authors neglect the hydrostatic pressure, so the force of attachment consists only of the capillary forces acting at the three phase contact line. The capillary force acting on the particle is

$$F_{ca} = -2\pi R_p \sigma \sin \omega \sin(\omega + \theta) \quad (26)$$

where θ is the contact angle of the three-phase system. Schulze makes the assumption to maximize both capillary forces by setting

$$\omega = \pi - \theta/2. \quad (27)$$

Equations 25 and 26 become

$$F_{\sigma} = \pi R_p^2 \left(\frac{2\sigma}{R_B} - 2R_B \rho_l g \right) \sin^2 \left(\pi - \frac{\theta}{2} \right) \quad (28)$$

$$F_{ca} = -2\pi R_p \sigma \sin(\pi - \theta/2) \sin(\pi + \theta/2) \quad (29)$$

The overall forces of attachment and detachment therefore can be expressed as

$$F_{Attach} = 6\sigma \sin(\pi - \theta/2) \sin(\pi + \theta/2) \quad (30)$$

$$F_{Detach} = 4R_p^2 \left(\Delta\rho_p g + \frac{1.9\rho_p \varepsilon^{2/3}}{(R_p + R_B)^{1/3}} \right) + 3R_p \left(\frac{2\sigma}{R_B} - 2R_B\rho_l g \right) \sin^2(\pi - \theta/2) \quad (31)$$

The value and nature of the three phase contact angle is a source of some contention. Some authors assume it to be that determined by the sessile drop method common to surface science characterization as described in Shaw (1992). However, Vinke et al. (1991) used equilibrium images of catalyst particles adsorbed to stationary bubbles to determine the maximum bubble coverage angle. They derived an expression for the three-phase contact angle. Their experimental results do not match those of classical goniometry measurements, such as those described in Shaw (1992).

2.5.5 Kinetic Modeling of Flotation

The probabilities of each subprocess can be combined to form kinetic constants for a population based kinetic model. The flotation process can be modeled as a reversible reaction (Gochin, 1990),

between the bubbles and the particles. The k_1 term is the rate constant of particle adsorption and k_2 is the rate constant of desorption. If the number of bubbles in the flotation cell remains constant and large, then the rate of formation for bubble/particle aggregates is a function of the number of particles and bubbles. The form of k_1 is

$$k_1 = Z P_C P_{ASL} P_{TPC} P_{Stab} \quad (32)$$

where Z is the number of bubble particle collisions per unit volume and time. Remember that P_c is the probability that a particle entering on a streamline within radius of R_B from the vertical with respect to the bubble will be contained in a streamline R_c away from the vertical. The parameter Z can be seen to be the rate at which a particle enters the R_B streamline. Liepe and Mockel (1976) determined this collision frequency empirically for small metal particles to be

$$Z = 2^{\frac{7}{9}} \frac{5}{3} \left(\frac{\varepsilon^{\frac{4}{9}}}{v_l^{\frac{1}{3}} \rho_l^{\frac{2}{3}}} \right) (R_p + R_B)^2 \left(R_p^{\frac{14}{9}} \Delta\rho_p^{\frac{4}{3}} + R_B^{\frac{14}{9}} \Delta\rho_B^{\frac{4}{3}} \right)^{\frac{1}{2}} \quad (33)$$

The apparent densities, $\Delta\rho_p$ and $\Delta\rho_B$, are the difference between the density of the fluid and the density of the particle and bubble, respectively. As the motion of the suspended particles is a strong function of their size and density, this expression may not be applicable to flotation deinking. The rate that particles desorb from the bubble surface is given by

$$k_2 = Z' P_{Destab} = Z' (1 - P_{Stab}) \quad (34)$$

Here, Z' is the rate at which the particles become destabilized. Heindel states “This term could be thought of as a collision rate between the bubble-particle aggregates and the “thing” that makes the aggregate unstable, like a turbulent eddy or another aggregate” (1997). The term is assumed to be the rate at which the destabilizing phenomena occurs, and can only be determined through experiment.

2.6 Purpose of This Research

This document will present the use imaging of particle / bubble interactions to better understand the phenomena of flotation. Some of the important process parameters will be examined by direct observation of particle to bubble interaction. The subprocesses important to successful flotation will be studied to evaluate the currently available models and theories. It is hypothesized that the flow behavior of the fluid between the particle and the surface of the bubble plays a role as important as the surface properties of the system.

CHAPTER 3

EXPERIMENTAL METHODS

The approach of this research was to use the experimental methods developed by Davies et al. (2000), Davies and Duke (2000), and Emerson et al. (2006) for the study of deinking flotation to investigate the fundamental phenomena important to the process. These methods are useful for examination of the important system parameters and for study of the fundamental subprocesses of flotation.

3.1 Experimental Apparatus

Two experimental apparatus were used: 1.) the stationary bubble tank, in which a stationary bubble is created and particles introduced so as to allow the study of the bubble / particle interactions and 2.) the suspended bubble flow facility, which simulates the rising of a bubble in a flotation cell. These facilities allow advanced imaging of the phenomena with high spatial and temporal resolution imaging equipment. The images can then be processed to allow observation of the data, or to quantify bubble coverage and particle sizes.

3.1.1 The Stationary Bubble Facility

Andrew Davies constructed the stationary bubble facility in 1998. The facility allows the analysis of particle / bubble interactions in a quiescent fluid. The interactions

are then imaged. The use of the stationary bubble facility has several advantages. The imaging system and particle solutions can be prepared and tested without the additional problem of a moving bubble. Also, the experiment time and cleanup are much easier with the stationary bubble facility, allowing fast studies of particle adsorption to be performed. Third, the surface forces involved in particle adsorption can be studied independent of the bulk fluid and surface fluid motions found in the suspended bubble column. This advantage can also be a weakness, as the flow field around a bubble is very important to each of the fundamental flotation subprocesses.

Figure 3.1 shows a schematic of the stationary bubble facility. A needle is placed in a quiescent fluid in a 3.5-liter clear plastic tank. It is then fed air very slowly from a KD Scientific 50-ml syringe pump (model number 210) to create and suspend a bubble at the tip of the needle but not allow the bubble to detach. A check valve prevents back flow of air. A pipette is then used to inject contaminant particles onto the bubble surface. The high-speed camera is used to record the injection.

The stationary bubble facility also allows for the stability of the adsorption of particles onto the bubble surface to be examined. By placing a stir bar in the stationary bubble tank and putting the tank onto a magnetic stir plate, adsorbed particles or networks can be imaged in the presence of flowing and turbulent flow fields. The Reynolds number of the flow, based upon the bubble size and the local velocity, can be varied considerably by the adjustment of the stirrer RPM. Reynolds number values (Re_B) similar to those found in a flotation cell, from 1 to 150, are easily obtainable.

Figure 3.2 shows three example images of stationary bubbles in different apparatus configurations. The first bubble is on the tip of a needle which is inverted in

the stationary tank. This configuration is best suited to qualitative study the effectiveness of system chemistry and particle size. It is also useful in observing the formation of particle networks and their stability. Figure 3.2b. is a bubble on the tip of a needle oriented upwards. This orientation is more appropriate for the study of the mechanisms of particle collision. Flotation modeling assumes that a particle approaches a bubble in a cylinder above the surface before striking the bubble or flowing around its surface; an obstruction, such as the needle, does not allow the observation of this process. Figure 3.2c is a high magnification image of the top of the bubble surface. This configuration is most useful in the study of the of the interaction between one particle and the bubble.

Figure 3.1: Stationary bubble suspending tank schematic.

Figure 3.2: Examples of stationary bubbles. a.) Stationary bubble on the tip of an inverted needle. b.) Stationary bubble on the tip of an upwardly oriented needle. c.) Higher magnification image of the surface of a stationary bubble.

3.1.2 The Suspended Bubble Facility

In order to better simulate industrial conditions, a bubble must be imaged in a flow field. A moving camera is not feasible, so the suspended bubble flow facility was created in 1998. A carefully controlled flow of water is used to keep a bubble in place in front of the imaging area by countering the buoyant motion of the bubble. By carefully controlling the flow of water, the buoyancy of the bubble can be matched, and the bubble will remain suspended in the flow field. The facility stands 9 feet tall and holds 8 liters of solution. Figure 3.3 shows a schematic of the flow facility.

The imaging column is a plexiglas pipe; it is held in place with flanges so that different columns may be used. A 1.5" (38 mm) pipe used to reduce the wall effects. The air is injected through medical grade needles and supplied directly from a compressed air cylinder. The flow from the cylinder and the needle size can both be altered to control the size and number of suspended bubbles. The water pump is a 1/8 HP Cole-Palmer Magnetic Drive Pump; it is rated at 3200 RPM and delivers 14 GPM (73 LPM) with 10 feet of head (3.05 m of H₂O). The rotometers are Cole-Palmer polysulfanone direct-reading in-line flowmeters with 316 stainless steel floats. There are three flowmeters in parallel to measure three different flow ranges: 0.1-1.0 GPM (0.37 – 3.7 LPM), 0.2-2.0 GPM (0.74-7.4 LPM), and 2.0-20.0 GPM (3.7 – 14.8 LPM). At the top of the column is a holding chamber that allows bubbles to leave the flow loop prior to reaching the pump. At the bottom of the holding chamber are vertical ¼ inch tubes that smooth the velocity profiles in the downflow entering the imaging column: Davies et al. (2000) determined that the flow will be fully developed at a distance of about 1 foot

(0.3m) down the length of the column. Therefore, all imaging occurs along the lower half of the column.

Figure 3.4 shows several different sizes of suspended bubbles and their terminal velocities. The smaller bubbles are more spherical than the larger bubbles, as expected. Larger bubbles require a higher flow rate in the column to be suspended. The bubbles may deform from a spherical shape and take a more elliptical shape. Davies et al. (2000) determined that the terminal rise velocities of the bubbles most closely match those found by theoretical modelling of flow around a rigid sphere. Most flotation modelling, especially that for deinking flotation, assumes a rigid sphere model for bubble flow.

Experiments involving the flow facility are performed much the same as those for the stationary facility. The desired chemistry is prepared and placed in the flow loop. Next, the water pump is turned on. Then, bubbles are released from the needle; the desired bubble size is controlled by the needle size and by the flow rate of air. The valve positions on the flow facility are controlled to suspend the bubble in the field of view of the camera. Particles are then introduced into the top of the column. The camera is often operated in “Center” mode, where data is continuously being recorded. As the camera memory fills, old data is replaced by new data. When an interesting event is observed on the monitor, the record command is entered. The camera then keeps some of the data prior to the recording and fills the memory with new data. For example, at 250 fps, the camera will keep 2.7 seconds prior to the record command and 2.7 seconds after.

The suspended bubble flow facility more closely models the flow fields of the bubble / particle system. As demonstrated in section 2.5, the flow field around the bubble is crucial to all facets of flotation modeling. By evaluating images from suspended

bubble experiments, the process scale parameters such as effect of particle size, system chemistry, and bubble size can be observed as well.

Figure 3.3: Suspending bubble flow facility schematic.

Figure 3.4: Example images of suspended bubbles of various sizes, their terminal velocities, and the flow rates needed to suspend them [Davies and Duke, 2000]. All bubbles are roughly spherical, with the larger sized bubbles becoming more ellipsoidal.

3.1.3 Particle to Bubble Collision Apparatus

In order to better examine the collision of a particle with a rising bubble, the particle to bubble collision apparatus was constructed. A bubble is created in a vertical piece of capillary tubing filled with fluid. Particles are released at the top of the capillary, and timed such that a bubble collides with the particles in view of the high-speed camera system. Figure 3.5 is a schematic of the particle to bubble collision apparatus. The apparatus stands 1.3 meters tall, and holds approximately 50 mL of solution.

The bubble rise area is a 1.0 meter glass tube, with an inside diameter of 5 mm. The tubing is attached to an air injection system and sealed at the bottom. Air is injected into the column by a syringe pump which produces bubbles through a Luer-lock medical needle. Bubble size can be controlled by a combination of flow rate and needle size.

To ensure that a particle – bubble collision is more easily viewed, a steady stream of rising bubbles is created in the tubing. Particles are introduced at the top of the apparatus. The camera is operated in “Center” mode; in this mode, the camera system, upon the record command, records the previous 1.3 seconds and following 1.3 seconds. When the particles fall in view of the camera, a movie sequence is recorded. Data from this apparatus is used to directly observe and estimate the probability of particle to bubble collision.

Figure 3.5: Particle to bubble collision apparatus schematic.

3.1.4 Imaging System

A high speed imaging system is used to analyze the adsorption of ink and glass particles onto the bubble surface. The camera used is a Kodak SR-500 Motion Corder Analyzer. The camera allows high temporal resolution by recording up to 1000 frames per second. Many of the experiments presented were performed at a speed of 250 frames per second. The camera has an image resolution of 512 by 480 pixels at 250 fps. The system has an online memory of 1365 frames, which, at 250 frames per second, corresponds to about 5.5 seconds of elapsed time. The shutter speed of the unit is controlled electronically to reduce motion blur. A tradeoff exists between adequate

lighting and shutter speed; the default speed of 250 Hz was suitable for the toner ink studies. The collision studies presented in section 4.2 required variation of the shutter speed from 500 to 1000 Hz to control the blurring caused by the motion of the glass particles. The Motion Corder outputs to a VCR and monitor for an analog copy of data and to a PC so that the collected frames can be captured and rendered into a video. Digital image output directly to the computer allows for image processing of individual frames with no loss in spatial or temporal resolution.

Several lens systems are available for use in this imaging system. A Micro-Nikkor 60mm AF close-up lens was used for much of the toner ink studies. This lens is very easy to use as the lighting is not difficult to arrange. This lens has a field of view of 9.7 cm^2 to wide shots of 25.8 cm^2 . It has a deep plane of resolution, making it best suited for the suspending bubble flow facility. Typical spatial resolutions for this lens system are 7 microns per pixel for the stationary bubble facility and 25 microns per pixel for the suspending bubble flow column. For the fundamental impact collision studies presented in Section 4.2 an Edmund Video Zoom Microscopic VZM 3001 was used. This lens allows for a more resolved close up image of the bubble surface. The depth of field of the lens is smaller, which can cause blurring of large particles. This lens has a magnification of up to three times, and a minimum field of view of 4 mm^2 . For much of this work the microscopic lens was operated at a magnification of 1.5 times with a field of view of 25 mm^2 . A typical image resolution is 5.5 microns per pixel. A very high magnification lens system consisting of a Questar QM 1000 MKII has also been used to image the behavior of adsorbed particles and particle networks very near to the bubble surface.

3.2 Preparation of Model Particles

The experimental facilities described above allow for the observation of many different types of particles. Several types of particles have been used in this work, including different inks, polymer contaminants, and glass beads.

3.2.1 Toner Particle Solution Preparation

The source of toner used for these studies was that used in laserjet printers. Two methods were used to prepare toner particles: scraping from toner printed transparencies, and grinding and fractionating from heat-set ink.

The scraped particles were obtained using the methods of Paulsen (1997). Overhead transparency films were printed with a full page of text by an inkjet printer using Hewlett Packard cartridges (Model 92298A). The transparencies were trimmed to remove the unprinted edges and soaked in distilled water for 3 hours. The toner was scraped off of the surface of the films using a metal spatula. The particles sink to the bottom of the collection vessel. Excess water over the particles was removed for ease of storage. Scraped ink particles were thin and planar, and vary greatly in size and shape.

Ground particles are obtained by heating toner powder in an oven at 80°C. The raw toner powder was obtained from Hewlett Packard cartridges (Model 92298A) intended for use in a LaserJet 4 high speed printer. Oven-baking fused the toner particles into a large solid block which was broken up by a hammer. The pieces of toner were then ground using a mortar and pestle and fractionated into different size categories using a Retsch AS 200 screening system. A series of screens with mesh sizes of 40, 60, 100,

and 200 were used. The particles were weighed and mixed with the desired water and surfactant solution. This procedure yields particles amorphous in shape, but of a similar size and general shape.

Both sources of toner have advantages and disadvantages. The scraped toner has a shape more similar to that found in the deinking process. The toner is also heat-set by the printer; the oven-cooking process may not simulate all facets of printing. However, there is no way to separate the scraped particles by size and the yield of particles is very small. Also, as the toner cannot be removed from the water solution, it is difficult to measure the amount of toner (on a dry basis) in the solution. Ground toner is easy to separate by size and easy to weigh on a dry basis. The shape of the larger ground toner particles does not correspond to that found in a flotation cell, however.

3.2.2 Glass Particle Preparation

Glass beads were used as model particles in the imaging studies.

Flotation modeling assumes that the adsorbing particle is spherical and that the surface and physical properties of the particles are known. Contaminant particles found in deinking flotation processes are often amorphous or large in aspect ratio. Their physical and surface properties vary with the grade of source paper and the printing process. Glass beads are useful in this regard as their physical properties are easily obtained. Particle size can be carefully controlled. The particles are spherical, making them more similar to the shape of particles used in flotation modeling. Surface properties such as surface contact angle of an air / glass / surfactant solution are well documented and easily measured. Amorphous glass particles can also be obtained by grinding and fractionating.

The glass beads used in this work (Product # G-9193, G-8893, and G-9268) were manufactured by Sigma for use in disintegration of microorganisms by grinding. Particle size ranges of less than 106 μm , 212 to 300 μm , 250 to 450 μm , and 425 to 600 μm were used. The particles were rinsed twice with distilled water and stored in distilled water prior to use. When the flotation chemistry was altered with a surfactant or the pH was adjusted, the particle fluid was similarly altered so that the chemistry of the water carrying the particles matched that of the flotation system. A typical injection contained 0.5 grams of glass particles.

3.3 Flotation System Preparation

Multiple system chemistries were used in this work. The procedure of Davies (2000) was used to prepare a fatty acid flotation chemistry based upon in-system creation of calcium oleate. Calcium oleate is an organic fatty acid-based surfactant commonly used in industrial flotation. In a flotation cell, calcium oleate breaks up into calcium and oleate ions. The oleate ions form oleic acid, which is the active surfactant in the system. Flotation with oleic acid in the presence of calcium ions is more effective than that with oleic acid alone. It is thought that the calcium ions promote ink agglomeration by binding the surfactant tails on the surface of the ink. This causes the ink particles to form into larger flocs (Beneventi and Carre, 2000).

Sodium oleate and calcium chloride obtained from Fisher Chemicals were mixed with distilled water at 40° C and stirred for 1 hour. The pH of the mixture was adjusted to 9.5 using dilute sodium hydroxide and hydrochloric acid. The solution was heated to remain at 40° C to prevent the calcium oleate from crystallizing. The concentration of

calcium oleate in the system was 100 mg/L. Typical prepared solution volumes were 3.0 L for the stationary bubble facility and 8.0 L for the suspending bubble flow facility. To evaluate the role of calcium ions in toner ink behavior at bubble surfaces, solutions of 100 mg/L sodium oleate were also prepared with no calcium chloride.

A model sulfonate based anionic surfactant system was also used. The solution was produced using sodium lauryl sulfate and sodium silicate. The preparation of the sodium silicate solution was similar to that for calcium oleate solution. A typical concentration of sodium lauryl sulfate in solution was 100 mg/L. To evaluate the role of calcium ions in toner ink behavior at bubble surfaces, solutions of 100 mg/L sodium lauryl sulfate were also prepared in the presence of 100 mg/L calcium chloride.

3.4.1 Movie Building

The camera on-board memory can save 1364 frames of time-stamped images. The amount of elapsed time depends upon the frame rate selected. Most of the images in this work were taken at a frame rate of 250 non-interlaced frames per second; this rate corresponds to about 5.5 seconds of observable event time.

The camera stores each of the frames as a separate file in Bitmap (BMP) format. This format allocates a set of color values to each pixel in an image, with no compression. As these images are in grayscale, the only color value needed is an 8-bit intensity value; values ranging from 0 (black) to 255 (pure white) are stored. BMP files are very large in size. Moreover, when these frames are combined to form movies, the movies themselves are much too large to deal with effectively (a full 1364 frame movie at maximum resolution can approach 700 megabytes). To reduce this size, the BMP files

are converted into a different digital image format, JPG using a Corel PhotoPaint 10 script. JPG files are compressed to a much smaller size than BMP files; in most cases, this compression causes little data loss, as the individual frames can be decompressed rather quickly. These JPG files are then formed into a digital video in the AVI format using Corel PhotoPaint 10 or Jasc Animation Shop 3. The conversion of the collection of individual frames into a single movie causes some small, but acceptable, loss of intensity resolution, with no loss in spatial resolution.

3.4.2 Quantification of Particle Adsorption

The amount of adsorbed particles on the bubble surface was quantified. For each experiment, an image was taken of an object of known length, typically a ruler, to obtain a spatial calibration. Typical resolutions for experiments were 7 μm per pixel in the stationary bubble facility and 25 μm per pixel in the suspending bubble flow facility. Image Tool, a freeware image analysis software package distributed by the University of Texas Health and Science Center, was used for quantification of the adsorption of adsorbed particles.

Individual frames from suspending bubble movies were used to find the size of the bubble, the area or volume of adsorbed ink, and the ink-free area of the bubble. Multiple still images were used for the quantification of each set of parameters.

The percent of the bubble covered by the ink is measured by determining the size of the bubble and the area of the bubble that is free from ink. The remaining area is assumed to be covered with ink. The fraction of bubble coverage is then found from

$$F_{Covered} = \frac{(A_{Bubble} - A_{Free})}{A_{Bubble}} \quad 3-1$$

where A_{Bubble} is the area of the bubble based upon the measure bubble radius and A_{Free} is the measured ink-free bubble area.

In a similar manner, the volume of adsorbed ink can be calculated by measuring the area of ink adsorbed in a frame from a suspended bubble movie. Figure 3.6 presents an overview of this process. First, the area of the adsorbed ink is added to the area of the bubble to get a total aggregate area. The effective radius of circle of an identical area is determined from equation 3-3:

$$A_{Total} = A_{Bubble} + A_{Ink} \quad 3-2$$

$$A_{Total} = \pi (R_{eff})^2 \quad 3-3$$

This radius is used to find the effective volume of the aggregate, which is used to obtain the effective volume of the adsorbed ink by subtracting out the volume of the bubble,

V_{Bubble} :

$$V_{Total} = 4/3 \pi (R_{eff})^3 \quad 3-4$$

$$V_{Ink} = V_{Total} - V_{Bubble} \quad 3-5$$

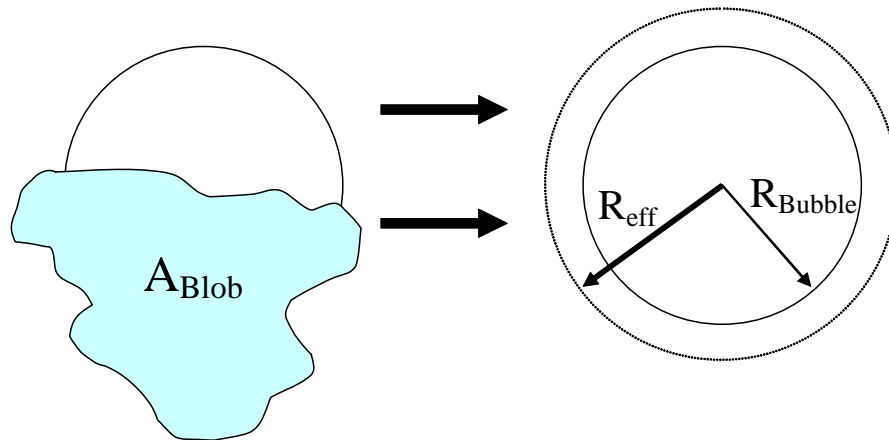

Figure 3.6: Illustration of calculation of adsorbed ink area.

The mass of adsorbed ink per bubble is then calculated by assuming the density and concentration of the adsorbed ink particles.

CHAPTER 4

VISUALIZATION RESULTS

This chapter focuses on the results of imaging experiments related to deinking flotation. Imaging of the interaction between particles and bubbles is shown to be useful in both the measurement of the effectiveness of system parameters and in studying the fundamental mechanisms of flotation. The effect of surfactant and particle size on flotation efficiency is examined by quantification of the amount of adsorbed ink on bubbles in the suspending bubble flow facility. The mechanisms of particle to bubble collision is studied for toner particles and for model glass beads using high-speed imaging of particles injected onto a stationary bubble surface.

4.1 Adsorption of Toner

The imaging of toner inks is useful in determining the effect of system parameters on the efficiency of flotation. By comparing measurements of percent bubble coverage and mass of adsorbed ink, the effectiveness of flotation system chemistries can be predicted.

4.1.1 Imaging of the Effect of Toner Particle Size and System Chemistry

Several different size ranges of toner particles were prepared by pulverizing and fractionating oven-cooked toner. Studies of the effect of particle size were done at stationary and suspending bubble surfaces in sodium oleate and sodium lauryl sulfate

surfactants in the presence and absence of 100 mg/L calcium chloride. Imaging of the effect of particle size was done by Emerson and Susanna Presta Maso (2003).

Descriptions of the video data files for the toner ink studies are presented in Appendix A.

Figure 4.1 presents frames from a movie to illustrate the injection of 75 to 150 micron oven-cooked toner in 100 mg/L sodium lauryl sulfate. The stream of injected particles strike the bubble and some attach to the bubble surface. The adsorbed particles orient themselves with the flow from the injection, and then slide to the bottom of the bubble. Figure 4.2 presents final images from several different injections of different sized particles for 100 mg/L sodium lauryl sulfate. The images in Figure 4.3 were taken from the end of injection movies for a solution of 100 mg/L sodium oleate and 100 mg/L calcium chloride. Adhesion of particles was observed in all cases. The adsorbed particles in the calcium oleate chemistry demonstrate the toner particle networks first observed by Bonometti (2001). The networks consist of particles adsorbed to one another by small contact points. As the fluid motion moves the networks, gaps between particles can be seen. No such networks were seen to form in the sodium lauryl sulfate / sodium silicate system.

Large toner particles were observed to adsorb to stationary bubbles by sharp contact points (Thompson 1997, Emerson 2003). Figure 4.4 is a high magnification image of a small particle adsorbed to a stationary bubble. The particle is attached securely by a single sharp point. Agglomerated toner particles also display such behavior when adsorbing to one another. Figure 4.5 is a high magnification image of an adsorbed toner network. The network structure is seen to be quite complex, with individual particles adsorbing to each other by sharp contact points. These networks are highly

mutable; individual particles are observed to rotate about the contacting points while leaving the network intact.

In order to investigate the role of calcium ions in the behavior of toner ink particles at bubble surfaces, additional studies were performed. Figure 4.6 presents final frames from the injection of 250 to 450 μm toner particles onto bubble surfaces for several different system chemistries. Figures 4.6 a. and b. compare the effect of calcium chloride with sodium oleate surfactant. Toner particle tails and networks were seen in the presence of calcium chloride, but not in its absence. To a lesser degree, similar behavior was observed for sodium lauryl sulfate surfactant.

The suspending bubble flow facility was used to image the adsorption of particles of different sizes in different flotation system chemistries. All suspending bubble movies were recorded 15 to 45 seconds after ink particles were introduced into the bubble column. The actual collision of a toner particle and a bubble was not observed, but many bubble/particle aggregates were imaged for each case. Figures 4.7 and 4.8 present two series of still images taken from several different suspending bubble movies. Figure 4.9 presents frames from suspended bubble sequences for several different chemistries. Adhesion of particles is seen for each particle size range in each system chemistry. No particle-free bubbles were seen for any system.

Figure 4.1: Frames from an injection of 75 to 150 μm toner particles onto the surface of a stationary bubble in sodium lauryl sulfate / sodium silicate chemistry. The particles remain adsorbed to the bottom of the bubble long after the injection.

4.1.2 Quantification of the Effect of Toner Particle Size and System Chemistry

Still images were used to quantify toner ink adsorption at bubble surfaces in the suspending bubble flow facility. The amount of adsorbed ink was measured by the methods described in section 3.4.2. The bubble surface coverage, volume of adsorbed ink, and mass of adsorbed ink per bubble were measured for the different toner particle size fractions in sodium oleate, sodium oleate + calcium chloride, sodium lauryl sulfate, and sodium lauryl sulfate + calcium chloride. Ten to fifteen bubbles were measured for each data point; multiple adjacent frames were measured for each bubble.

The density of adsorbed toner ink has not been determined. The amount of water absorbed by the toner particles is not known. Additionally, as seen in Figure 4.5, toner particle networks often have large voids in them. An ink density of 1.1 g/mL and an ink in toner network concentration of 50 % was assumed for these measurements. Figure 4.10 is a plot of mass of adsorbed ink per particle size for both system chemistries. The mass of ink increased as particle size increased.

Figure 4.10 presents a plot of the estimated mass of adsorbed ink on the bubble surface for the four system chemistries. For each surfactant system, the mass of attached ink particles increased as the particle size increased. For sodium oleate + calcium chloride, the mass of ink per bubble increased from 5.7 mg to 12.5 mg. Without calcium, the mass of ink per bubble increased from 2.95 mg to 6.15 mg. For sodium lauryl sulfate + calcium chloride, the mass of ink per bubble increased from 4.4 mg to 7.7 mg; in the absence of calcium chloride, mass of ink increased from 3.1 to 6.1 mg. There appears to be no significant difference between the two surfactants in the absence of calcium chloride. For both sodium oleate and sodium lauryl sulfate, a significant

increase in adsorbed ink was observed in the presence of calcium chloride. Sodium oleate with calcium chloride promotes the most toner ink adsorption of the systems studied.

The effect of calcium on toner ink adsorption was also studied in clear water. Figure 4.11 presents quantification results for the attachment of toner ink particles to suspended bubble surfaces in clear water at a pH of 9.5 in the presence and absence of 100 mg/L calcium chloride. No significant difference between the two systems was observed. Very little adsorption was observed for each system for all particle size ranges. It should be noted that the amount of adsorbed ink for the surfactant-free experiments is close to the minimum that can be discerned by the visualization methods used.

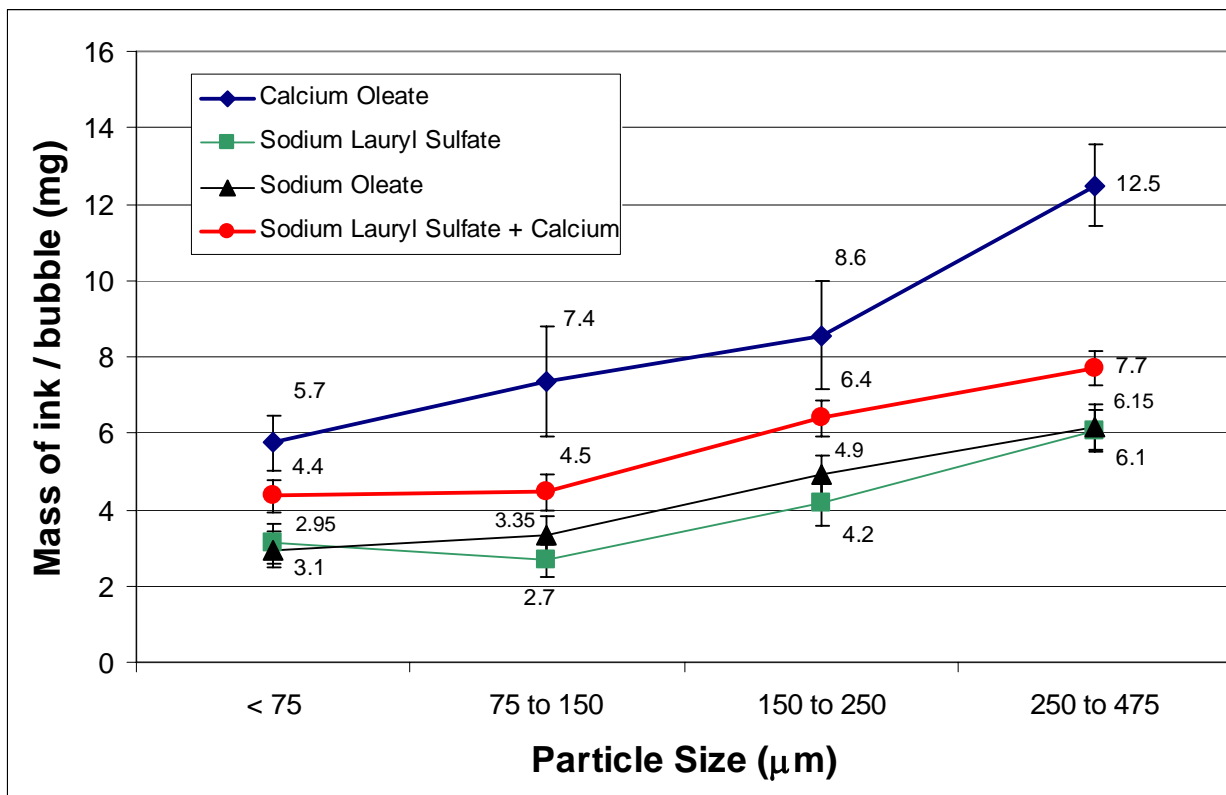

Figure 4.10: Estimated mass of ink adsorbed per bubble for four system chemistries and four particle size ranges.

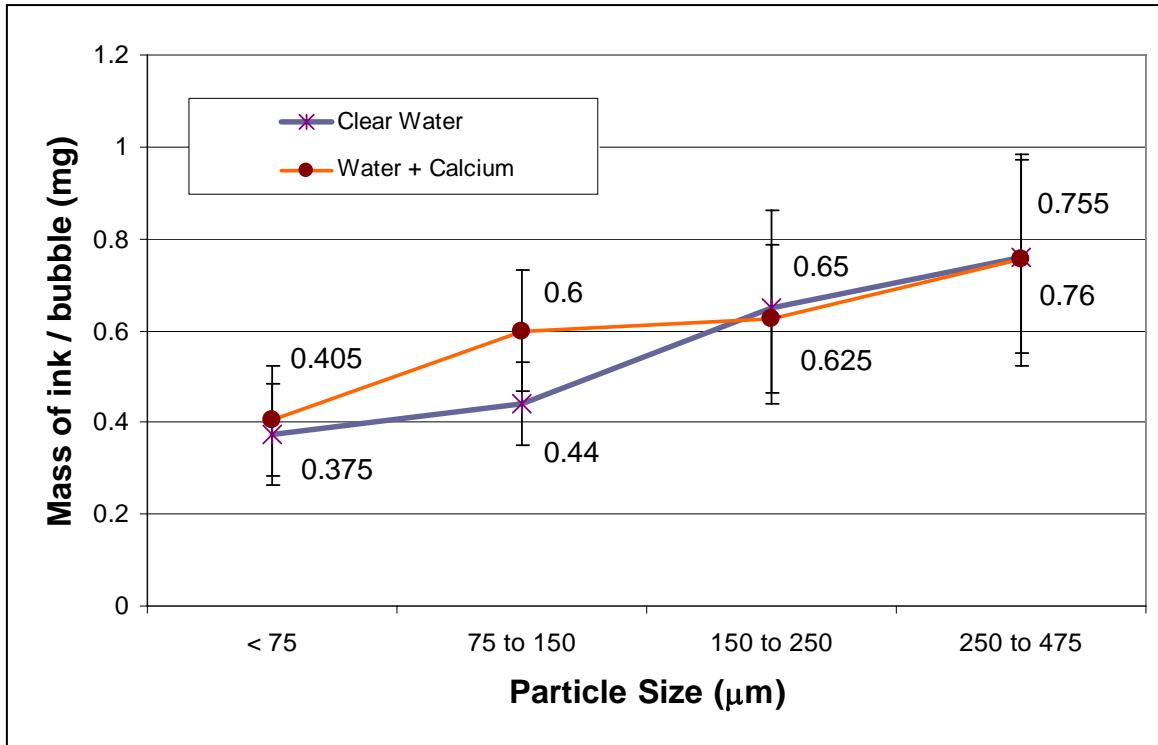

Figure 4.11: Mass of toner ink adsorbed per bubble for clear water at pH = 9.5 in the presence and absence of calcium chloride.

4.2 Adsorption and Collision of Model Glass Particles

Flotation modeling generally assumes that adsorbing particles are spherical. In order to better compare experiments to models, spherical glass beads of varying size ranges were used for visualization studies. The physical properties and surface properties for glass beads are well established and easy to obtain. They are therefore very suitable for fundamental studies of the mechanisms of flotation.

High speed imaging was used to study the behavior of untreated fine glass spheres at bubble surfaces. Particle size ranges of 425 to 500 microns, 225 to 300 microns, and less than 106 microns were used to resemble the toner particle size studies. The silicate beads were untreated and found have a contact angle of 105° by the sessile drop method. A listing of the glass bead movies are presented in Appendix A.

Figure 4.12 shows a sequence of images from a video of an injection of fine (less than 106 microns) glass beads onto a bubble surface in the calcium oleate system chemistry. The surfactant concentration is 100 mg / L. The stream of particles (beads) strike the bubble surface and some particles adsorb to it. A small amount of adsorbed particles remain on the bottom of the bubble surface in what appears to be a monolayer after the injection. The bead layer does not fall off. In Figure 4.13, a bubble in calcium oleate solution is shown with a layer of adsorbed particles (106 microns).

Larger size glass particles do not appear to adsorb to the bubble surface for either calcium oleate or lauryl sulfate chemistry. Figure 4.14 shows images from a movie of an injection of 225 to 300 micron particles onto a bubble in water at a pH of 9.5. Particles strike the bubble, slide around the bubble surface, and fall to the bottom of the vessel. They do not attach to the bubble surface.

No adsorption was observed for the 425-500 sized particles (Figure 4.15). These particles appeared to bounce off of the surface of the bubble and fall out of the frame. In order to better track the behavior of the particles, the recording speed was changed from 250 to 1000 fps. Figure 4.16 shows a sequence of frames from a 1000 fps video of an injection of the large glass particles. An example particle is highlighted as it strikes the bubble, dimples the bubble surface, and bounces away from the bubble. The elapsed time for this event is about 5 milliseconds.

High speed images of the top of a bubble as the particles impact the bubble surface were used to better characterize their behavior. For consistent analysis, the different particle size ranges were injected onto the same bubble. The large particles were injected first, and the video showed that the particles would not remain on the bubble surface and interfere with the flow field. Figure 4.17 shows a sequence of frames from a movie of an injection of $< 106 \mu\text{m}$ glass beads. The particles travel in chaotic streamlines which flow around the bubble surface. No particles were seen striking the bubble, but some traveled close to the bubble surface. The images in Figure 4.18 are from a movie of 225 to 300 μm glass particles. These particles demonstrated two different behaviors: some bounced off of the bubble surface, while some struck the bubble and rolled along it out of the frame. The frames in Figure 4.19 are from an injection of the 425 to 500 μm particles. Particles near the bubble struck it and were deflected away. Notable bubble deformation (dimpling) was observed. After the collision the bubble surface quickly reforms.

A particle must remain on the bubble surface until it reaches the bottom of the bubble for stable attachment to occur. The particles in Figures 4.17 and 4.18 which roll

along the bubble surface should therefore continue to do so when the image focus is on the side of the bubble. Figure 4.20 shows a single small particle ($\sim 45 \mu\text{m}$) strike the bubble surface and roll along the bubble surface to the bottom of the bubble. This particle would probably remain attached to the bottom of the bubble were it visible. The side view in Figure 4.21 is from an injection of 225 to 300 μm particles. The beads strike the top of the bubble and some of them roll along the surface. When the particles reach the downstream side of the bubble, they leave the bubble surface. Figure 4.22 presents images from a movie of an injection of 425 to 500 μm particles onto a bubble surface. All of the particles bounce off of the bubble; none are seen sliding or rolling along the surface of the bubble.

If a particle slides or rolls along the bubble surface, then attachment by sliding may occur. The thin film between the particle and the bubble will drain as the particle moves along the bubble surface. If this film drains sufficiently, the particle will adsorb to the bubble surface. If a particle directly impacts the surface, and additional force is introduced. The bubble will reform the impacted surface, which will result in a repulsive force being placed on the particle. If a particle has sufficient attractive forces to overcome this repulsion, the particle will adsorb to the surface. However, particles that do not adsorb at the instant of impact collision (such as those in Figures 4.15 and 4.22) will be bounced away from the bubble to such a distance that adhesion by sliding cannot occur.

Figure 4.23 presents frames from an injection of 212-300 μm glass beads in the particle – bubble collision apparatus. The indicated particle approaches the rising bubble, but does not strike it. It appears to follow the streamline around the bubble until

it passes out of range. Figure 4.24 presents frames from an injection of a large number of 212-300 mm glass beads into the particle – bubble collision apparatus. Many particles are seen to approach the bubble; some of the particles strike the bubble surface. Data from this sequence and similar sequences is used to estimate the probability of particle to bubble collision.

CHAPTER 5

DISCUSSION OF VISUALIZATIONS

5.1 The Effect of System Chemistry and Particle Size in Flotation

Calcium based fatty acid chemistry has been widely used in industrial flotation for many years. Flotation based upon fatty acid surfactants has long been known to perform better in the presence of calcium than without it, although it is unknown why (Beneventi and Carre, 2000). It is thought that calcium ions allow ink particles to form agglomerates which increase the mass of ink that may be carried by each bubble, although the mechanism of this phenomenon is not certain (Pugh and Rutland, 1997). Also, it has been postulated that the calcium ions allow ink to more readily adhere to the bubble surface (Drenlich et al. 2001).

The toner particle networks seen in figure 4.3 appear to support the theory that calcium ions lead to particle agglomeration at the bubble surface. The results presented in figures 4.10 and 4.11 appear to support each of these theories, and to elucidate the mechanism of ink particle agglomeration. Figure 4.10 demonstrates that, for all particle sizes, and each surfactant, a larger mass of toner adsorbs to a bubble surface in the presence of calcium ions. In clear water, however, no change in attached ink mass and no toner ink agglomeration are observed. This suggests that the mechanism of ink particle agglomeration illustrated by Rutland and Pugh in Figure 2.2a does not occur for toner ink particles.

The results from figures 4.10 and 4.11 also give some insight into the effect of particle size on the flotation of toner ink. While the fraction of bubble covered by ink did not change significantly for the different particle sizes, the volume and mass of ink adsorbed increased as particle size increased. The difference can be explained by the fact that the larger particles have more mass, but may still only adsorb to the same bubble area. It is unknown why the particle size does not affect bubble coverage. The amount of ink particles per bubble in the system was much higher than in industrial conditions (we are essentially assuring that some particle collisions occur). The results suggest that ink particle size controls the likelihood of collision, but does not greatly affect the degree of particle attachment once collision occurs.

5.2 Study of the Mechanisms of Particle to Bubble Collision

The fact that the smallest glass particles adsorb to the bubble and the larger sizes do not is at first perplexing, as the surface properties of the beads are the same. However, Schulze (1992) postulates that two mechanisms of adsorption exist, with each being applicable to different sized particles of identical material. He states that the Stokes number for the particle / bubble system is a parameter that can be evaluated to determine which mechanism is appropriate. The Stokes number (St) is defined, generally, as the ratio of the inertial forces of the particle to the viscous drag force on the particle due to the flow of the fluid film around the bubble:

$$\text{St} = \frac{\rho_P d_P^2 v_P}{9 \mu d_B} = \frac{\text{Re}_B \rho_P d_P^2}{9 \rho_W d_B^2} \quad 4-7$$

where Re_B is the Reynold's number of the bubble based upon the rise velocity of the bubble, d_p is the diameter of the particle, ρ_w is the density of water and d_B is the diameter of the bubble. For identical bubble, water and particle properties, the Stokes number depends only upon particle size. For a very small Stokes number (less than 0.1, such as for fine or light particles) the viscous drag on the particle dominates the particle motion. These particles will follow the fluid stream lines around the bubble surface and will never strike it. The mechanism of attachment for these particles is film thinning and drainage, as described in section 2.5.2.1. However, if the Stokes number is greater than 1, the inertia of the particle dominates its motion; the collision mechanism in this regime is called impact collision. A particle approaching the bubble surface will not follow the streamline around the bubble, but instead will strike and deform the bubble surface. The bubble will reform and force the particle away, causing it to "bounce." If the particle forms a stable three-phase contact point before being forced away, adsorption occurs. Otherwise, the particle is forced away from the bubble. If the Stokes number lies between 0.1 and 1, then both mechanisms have varying degrees of importance. By assuming that the particles are at their terminal settling velocity (experimentally confirmed for the larger particle sizes), the Stokes number for each particle size can be found. The Stokes equation for the settling velocity of a sphere is

$$v_p = \frac{(\rho_p - \rho_w) g d_p^2}{18 \mu} \quad 4-8$$

In this equation the settling velocity of the particle, v_p is calculated from ρ_p and ρ_w , the densities of the particle and water, g , the gravitational constant, d_p , the diameter of the particle and μ , the viscosity of water. A glass specific gravity of 2.5 and an assumed

bubble size of 1.0 mm was used to calculate the Stokes number for several particle size ranges. The results of these calculations are presented in Table 5-1:

Glass Particle Size	Stokes Number
< 106 μm	< 0.05
225 – 300 μm	0.095 – .29
425 – 500 μm	12 – 23

Table 5-1: Stokes Number for Various Particle Size Ranges for Glass Beads

The smallest particle size range, less than 106 microns, gives a Stokes number of less than 0.05, which is well within the attachment by sliding range. The next size range is within the intermediate realm, but is more closely located by the sliding regime. The largest size range is entirely within the impact collision regime.

For smooth spheres, the probability of attachment by impact collision is much lower than that for attachment by sliding, even for particles that are highly hydrophobic. Schulze reports that the probability of adhesion by collision for very hydrophobic particles decreases as the particle size increases. For slightly hydrophilic particles, such as beads used in this study, the probability of attachment by impact collision is negligible.

The results presented in 4.2.1 confirm Schulze's analytical predictions that spherical particles with relatively large Stokes number values bounce off of the surface of a bubble and are thus less likely to adsorb. The path of the particles that are smaller than 106 μm is governed by the streamlines of the flow. They roll or slide along the bubble and are the particles which are seen to adhere to the bubble surface. The largest particles,

425 to 500 μm , bounce off of the surface and do not adsorb. The medium (225 to 300 μm) particles exhibit both flow behaviors, but do not attach to the bubble due to inertia.

5.3 Study of Toner Particle Impact and Collision

The analysis presented for glass beads was applied to toner inks as well. The major differences between toner particles and glass particles are toner is much less dense and toner is far more hydrophobic. However, the Stokes number criterion does not include any term that would depend upon the hydrophobicity of the toner particle surface. Indeed, such a term is unnecessary, as the criterion is used to predict how the particle behaves as it approaches and strikes the bubble surface and not the degree of affinity the particle has for the surface. Another important difference is the fact that while the model glass particles are spherical, the toner particles are not.

Similar calculations were performed for the toner ink particle size ranges studied in section 4.1. The terminal settling velocity was calculated assuming spherical particles and an ink specific weight of 1.5. The results of these calculations are presented in Table 5-2:

Toner Ink Particle Size	Stokes Number
< 75 μm	< 0.0003
75 – 150 μm	0.0003 – 0.0055
150 – 250 μm	0.0055 – 0.042
250 – 475 μm	0.042 – 0.55

Table 5-2: Stokes Number for various particle sizes of toner ink.

As seen in Table 5-2, the Stokes number values for toner are much smaller than those for glass beads. Only the largest toner particle size gives a Stokes number that lies outside

the attachment by sliding regime. The 250 to 475 μm particle size range lies partly within the transition regime. It should be noted however, that the film drag on an amorphous particle is larger than that on a sphere of the same size (Happel and Brenner, 1983), so the terminal velocities used in the above calculations are the maximum possible for the indicated particles. The actual settling velocity is probably much lower. Also, the density of toner ink in water is unknown (assumed here to be the dry value of 1.5 g/mL), but is thought to be very close to that of water. As the density of ink approaches that of water, the Stokes number approaches zero. The Stokes number values in Table 5-2 are therefore a maximum possible value for the toner particles; the actual values are probably lower.

From the data presented in Table 5.2, predictions on the behavior of toner ink as it collides with the bubble surface can be made. For ink particles ranging up to 300 microns in size, the particles should follow the streamlines. The particles will not actually collide with the bubble surface, but will instead slide around the bubble. For particles larger than 300 microns, viscous streamline flow will still dominate, but some impacting of the surface of the bubble may be observed. Imaging of the bubble surface during the injection of different particle sizes supports these predictions. Figure 5.1 presents frames from the imaging of 125 to 250 μm toner particles onto the top of a stationary bubble. The particles follow the fluid flow and do not impact the bubble surface. The particle shown in Figure 5.1 does not collide with the bubble, but instead flows around it; a thin film between the indicated particle and the bubble can be seen in Figures 5.2.b and 5.2.c. However, the large particle in Figure 5.2 does appear to impact the surface of the bubble. The particle approaches the bubble, strikes the surface, and

bounces. It then slides along the surface of the bubble until it falls out of frame. There is no evidence of the particle being rejected as the bubble reforms, so this particle may be in the similar intermediate range as the glass beads in Figure 4.18, or it may form a stable impact adhesion before being ejected. This particle also appears to be adsorbed to another toner particle. The added inertia or drag of the attached particle may prevent the impacting particle from bouncing off of the bubble surface.

Toner ink particles are seen to follow the same Stokes number criterion as glass beads. The analysis of Schulz predicts that attachment by sliding is the predominant mechanism of toner ink adhesion, and this prediction has been confirmed by high speed imaging. It is predicted that larger toner particles (~ 600 microns for an ink particle density of 1.1 g / mL) will have impact collisions with the bubble surface, and therefore may not adsorb as readily as more moderately sized ink particles.

Figure 5.1: Sequence of images from the injection of 125 to 250 micron toner particles. The indicated particle approaches the bubble surface, but does not appear to strike it. The indicated particle stalls on the top of the bubble in b.) before falling out of view in d.)

Figure 5.2: Sequence of images from an injection of large (250 to 450 microns) toner particles. The indicated particle impacts the bubble surface in c.) and bounces, but is not repelled away from the bubble surface.

CHAPTER 6

EVALUATION OF FLOTATION MODELS

The probabilities associated with each important flotation subprocess were presented in Section 2.5. These probabilities can be combined to obtain an estimate for the overall probability of particle adsorption using Equation 1.

$$P_{Overall} = P_c P_A P_{TPC} P_{Stab} \quad (1)$$

In this section we will use observations and measurements from the visualization studies to estimate or evaluate the probabilities associated with each subprocess.

It should be noted that several of the assumptions made in the development of the models presented in Section 2.3 do not apply to the experimental system or to the general deinking flotation system. The assumption of one particle per bubble is not valid. Flotation contaminant particles are not usually spherical and are not always much smaller than the bubble size.

6.1 Flotation Modeling Calculations

Not all of the parameters pertaining to the author's experimental system are known, but probabilities for each of the subprocesses have been estimated based upon best available data. The results of the model calculations are presented in Table 6.1.

Probability of Collision

The probability of particle collision was estimated from equation 6:

$$P_C = \left(\frac{3}{2} + \frac{4 \text{Re}_B^{0.72}}{15} \right) \left(\frac{R_P}{R_B} \right)^2 \quad (6)$$

Four particle size ranges, corresponding to the toner particles discussed in Section 4.1, were used. The average diameter within a range was used in the model equations.

Assumed bubble and water properties are presented in Table 6-1.

. Bubble and Water Properties	
Bubble Diameter	1 mm
Bubble Rise Velocity	0.148 m/s
Density of Water	992 kg/m ³
Viscosity of Water	0.6560 cp
Bubble Reynolds Number	224

Table 6.1: Properties used in P_C calculations.

The probability of collision for the four particle size ranges are $P_C = 0.015$ for a particle size of 36 μm , $P_C = 0.133$ for a particle size of 113 μm , $P_C = 0.42$ for a particle size of 200 μm , and $P_C = 1.29$ for a particle size of 350 μm . The calculated probabilities of capture follow the expected relationship of increasing as particle size increases, or more generally, increasing as the ratio of particle size to bubble size approaches unity.

However, the probability for the largest particle size is much greater than unity. This could indicate a 100 percent chance of particle collision, or it indicates that this particle size is far outside the range of this model's applicability.

Probability of Attachment by Sliding

The probability of attachment by sliding was estimated by using equation 16:

$$P_{ASL} = \sin^2 \left\{ 2 \arctan \exp \left[\frac{-(45 + 8 \text{Re}_B^{0.72}) v_B \tau_i}{30 R_B \left(\frac{R_B}{R_p} + 1 \right)} \right] \right\} \quad (16)$$

This equation requires an estimate for the particle induction time, which is not available.

The closest analogue to ink particles for which data is available is coal. Wang et al. (2004) present a model for the estimation of the induction time and also present some experimental measurements of this value for several different substances, including different grades of coal. The particle induction time is dependant upon the particle size.

Table 6.2 summarizes the parameters used.

Bubble Reynolds Number	223
Bubble Radius	0.5 mm
Bubble Rise Velocity	0.148 m/s
Particle Induction Time	
36 μm	5 ms
113 μm	10 ms
200 μm	20 ms
350 μm	35 ms

Table 6.2: Properties used in P_{ASL} calculations.

The probability of adhesion for the four particle size ranges are $P_{ASL} = 5.7 \times 10^{-1}$ for a particle size of 36 μm , $P_{ASL} = 6.3 \times 10^{-4}$ for a particle size of 113 μm , $P_{ASL} = 1.2 \times 10^{-12}$ for a particle size of 200 μm , and $P_{ASL} = 3.1 \times 10^{-34}$ for a particle size of 350 μm . This data gives the expected relation that probability of adhesion by sliding decreases as particle size increases. However, the probabilities for the largest particle sizes are orders

of magnitude lower than those measured by Schulze (1989). The two lowest size ranges match the results of Schulze within an order of magnitude. The error is probably in the induction time estimates and in the application of the model; Schulze states that this model only applies to small particles (<150 μm). Experimental results show that particles in all of these size ranges adsorb quite readily.

Probability of Formation of Three-Phase Contact Point

The probability of the formation of the three-phase contact point is assumed to be unity for all particle sizes. This assumption is made by Schulze (1989), Heindel (1997), and other authors (Dai et al. 2000; Yoon, 1991). Conditions that give a non-zero P_{ASL} are assumed to result in a P_{TPC} equal to one. No issues with this assumption are known.

Probability of Attachment Stability

Heindel's 1997 development presented in Section 2.3.4 was used to estimate the probability of particle stability from the forces of attachment and detachment.

$$F_{Attach} = 6\sigma \sin(\pi - \theta/2) \sin(\pi + \theta/2) \quad (30)$$

$$F_{Detach} = 4R_p^2 \left(\Delta\rho_p g + \frac{1.9\rho_p \varepsilon^{2/3}}{(R_p + R_B)^{1/3}} \right) + 3R_p \left(\frac{2\sigma}{R_B} - 2R_B\rho_l g \right) \sin^2(\pi - \theta/2) \quad (31)$$

$$P_{Stab} = 1 - \exp\left(1 - \frac{F_{Attach}}{F_{Detach}}\right) \quad (18)$$

The turbulent energy density was assumed to be 50,000 mm^3/s^2 (Schulze, 1989). The three-phase contact angle is assumed to be 110 degrees; this value has been measured for a flat surface using imaging techniques. The surface tension is assumed to be equal to 25

dyne/cm for sodium oleate solution (Shaw, 1992). The probability of adhesion stability for the four particle size ranges are $P_{Stab} = 0.78$ for a particle size of 36 μm , $P_{Stab} = 1.00$ for a particle size of 113 μm , $P_{Stab} = 1.00$ for a particle size of 200 μm , and $P_{Stab} = 1.00$ for a particle size of 350 μm .

These values are reasonable and match those presented by Schulz for hydrophobic particles. The stability is expected to decrease as particle size increases, but to remain significantly close to unity. The values for the collision and adhesion probabilities point out the need for better models and evaluation methods for the model parameters.

By combining these probabilities, the total probability of flotation is calculated from equation 1. The probabilities for the three sub-processes, overall probability of flotation, and representative images of toner particles adsorbed to bubble surfaces are presented in Table 6.3. The smallest particle size range has a $P_{Overall}$ with an order of magnitude of 10^{-2} , while the largest range has an order of magnitude of 10^{-34} . The overall flotation probability value is dominated by the probability of adhesion for all but the smallest particle size range. In our experiments, many particles are observed to adhere to a bubble for all particle sizes. Observed estimates for the probability of flotation, $P_{Overall}$, are on the order of magnitude of 10^{-1} .

The results of these models, when applied to the authors system of interest, do not match qualitative experimental results. The particle sizes of our system may lie too far outside the realm of the validity of these models. Experimental results suggest that some of the assumptions inherent to these models do not apply to the author system. The following section will present results from efforts to divorce the sub-processes from one another and to directly measure them.

	$< 75 \mu m$	$75 - 150 \mu m$	$150 - 250 \mu m$	$250 - 450 \mu m$
P_C	0.015	0.13	0.42	1.00 (1.3)
P_{ASL}	5.7×10^{-1}	6.3×10^{-4}	1.2×10^{-12}	3.1×10^{-34}
P_{Stab}	0.78	1.0	1.0	1.0
$P_{Overall}$	6.7×10^{-2}	8.4×10^{-5}	5.0×10^{-13}	3.1×10^{-34}
				

Table 6.3: Results of model calculations for toner ink for four particle size ranges and representative images.

6.2 Visual Estimation of Adhesion Subprocesses

Data from toner injection movies in calcium oleate chemistry was used to directly estimate the probability of the three particle to bubble adhesion subprocesses. These visual estimations were then compared to the calculations from Section 6.1 to evaluate the effectiveness of the models.

Sequences from toner injections in the particle to bubble collision apparatus were used to estimate the probability of collision. Particle to bubble collision is an entirely fluid flow related phenomena, so no surfactant was used in these experiments; the lack of surfactant also effectively removed the probabilities of adhesion and stability from consideration, allowing observation of the single phenomena of particle to bubble collision. A manual count of particles that collided with the bubble and those that did not was used to estimate the probability. The criteria for a colliding particle was determined to be those particles that approached the bubble and either collided with or followed the streamlines around the bubble. The probability of collision for toner particles of 150 – 250 nm in size was estimated to be 58%. As the diameter of the capillary tubing is comparable to the bubble size, this method does not discount wall effects; the large number of particles in the injection also creates the possibility of particle to particle interactions which may effect the estimations.

Sequences from toner injections in the stationary bubble facility were used to estimate the probability of particle adhesion. In most cases, a large number of toner particles were injected onto the surface. In effect, these experiments force the particle to bubble collision probability to 100%. A manual “eye-count” of particles that adhered and those that did not was used to estimate the probability of adhesion. The criteria for an

attached particle was determined to be those particles that struck or slid along the bubble surface and remained adsorbed at the bottom of the bubble, for any length of time.

Particles which adsorbed to other particles on the bubble surface were not considered.

The probability of attachment for toner particles of 150 – 250 μm in size was estimated to be 35 %. When considering particles which attach to other particles, the probability of adhesion rose to greater than 50%. Injections varied greatly in number of injected particles, speed of injected flow, and angle of injection onto the bubble surface.

No particles were ever seen to detach from the surface of stationary or suspended bubbles. When agitation was applied to adsorbed toner networks, no particles were seen to detach from the bubble surface or from the network. The estimated value for the probability of stability for toner particles of 150 – 250 μm in size is 100%.

Table 6.4 presents a comparison of the sub-process probabilities calculated in Section 6.1 and the values estimated from direct imaging. The visually observed and calculated probabilities of collision are relatively close in value. The probabilities of adhesion differ greatly. The calculated and observed probabilities of stability are both found to be 100%. The overall probabilities differ by twelve orders of magnitude. The major contributor to the difference between the observed and calculated probabilities is the probability of adhesion. Possible sources of error in the adhesion model are particle shape and model parameter estimates.

	P_C	P_{ASL}	P_{Stab}	$P_{Overall}$
Visualizations	0.58	0.35	1.00	0.20
Modeling Calculations	0.42	1.2×10^{-12}	1.00	5.0×10^{-13}

Table 6.4: Comparison of results of imaging estimations to model calculations for the probability of the subprocesses of particle to bubble adhesion. Results are for toner ink particles of 150 to 250 μm size in calcium oleate chemistry at a pH of 9.5.

CHAPTER 7

CLOSURE

Imaging techniques were used to study particle to bubble adhesion in toner deinking flotation systems. Direct observation of particle behavior at bubble surfaces has helped to elucidate the role of process conditions and parameters on deinking operation, examine some of the fundamental interactions between particles and bubbles, and to evaluate the current flotation models.

Imaging techniques have proven effective in quantification of the role of particle size and surfactant in flotation. Flotation efficiency, in terms mass of ink per bubble, was seen to increase as toner particle size increased. Bubble coverage was not seen to vary significantly with particle size. Particle to bubble adhesion for toner inks and toner ink complexes was observed to be very stable. Calcium ions were observed to promote more particle adsorption, in terms of both bubble coverage and mass of ink per bubble, for both sodium oleate and sodium lauryl sulfate surfactants. Calcium ions had no discernable effect on the adsorption of toner inks to bubbles in surfactant-free systems; the first of the particle agglomeration mechanisms proposed by Pugh and Rutland (1997) did not hold in this system.

The collision of particles with a bubble surface was also studied. Impact collisions were directly observed for particles with Stokes number greater than one, while sliding collisions were observed for particles with a Stokes number less than one. This

phenomenon confirms the criteria proposed by Schulze for prediction of the mechanisms of particle / bubble collisions.

Theoretical flotation models were used to calculate predictions for the probability of flotation of toner inks. Estimates for the probability of each of the three flotation sub-processes were found for four size ranges of toner particles. The estimates did not match qualitative experimental observations. New methods for the direct visual measurement of the three sub-processes were developed. Visual estimates for the probability of collision and probability of stability matched the model predictions. However, the results of the Yoon model for the probability of particle adhesion are many orders of magnitude smaller than observed. Current flotation models do not account for non-spherical particles, multiple particles adhering to a bubble, and particle agglomeration at the bubble surface.

A better understanding of particle to bubble adhesion is important to flotation separation operations, slurry reactor systems, environmental/biological systems, and multi-phase flow in general. This work has helped to advance the state of experimental measurements in particle to bubble interactions in deinking flotation. The work has confirmed several previous theoretical predictions and has identified areas of weakness in the theoretical development. A better understanding of how the theoretical work relates to experimental results would greatly advance the understanding of this important phenomena.

APPENDIX B

The particle-bubble adhesion model developed by Vinke et al (1991) was used to examine the role of particle shape in the attachment of particles to bubble surfaces. This model uses visual measurements for the maximum bubble coverage angle to estimate the three-phase contact angle between an individual particle and a bubble in a liquid system. The three-phase contact angle is illustrated in Figure B-1.

Figure B-1: Illustration of the Three- Phase Contact Angle (θ).

The stationary bubble facility was used for this study. A bubble was produced from an inverted needle in the tank. Particles were carefully injected onto the bubble until no additional particles would adhere to the surface. The angle of coverage of the “cap” of adsorbed particles was obtained from visual measurements. This measurement was used to estimate the effective three-phase contact angle.

Figure B-2 presents results from adhesion measurements for glass particles.

Figure B-2a shows the attachment of spherical glass particles less than 75 microns in size, while Figure B-2b shows the attachment of amorphous ground glass particles of less than 75 microns.

Figure B-2: Measurement images of the maximum coverage angle for glass particles. a.) Spherical glass particles <75 microns. b.) Amorphous glass particles <75 microns.

The maximum coverage angle increases from 40° to 80° when the particles are not spherical. These measurements correspond to three-phase contact angles of 50° and 71° . This verifies the theory that amorphous particles will adhere to the surfaces of bubbles more readily than spherical particles.
